

# PriFHEte: Achieving Full-Privacy in Account-based Cryptocurrencies is Possible

Varun Madathil and Alessandra Scafuro \*

North Carolina State University

**Abstract.** In cryptocurrencies, all transactions are public. For their adoption, it is important that these transactions, while publicly verifiable, do not leak information about the identity and the balances of the transactors.

For UTXO-based cryptocurrencies, there are well-established approaches (e.g., ZCash) that guarantee full privacy to the transactors. Full privacy in UTXO means that each transaction is anonymous within the set of all private transactions ever posted on the blockchain.

In contrast, for account-based cryptocurrencies (e.g., Ethereum) full privacy, that is, privacy within the set of *all accounts*, seems to be impossible to achieve within the constraints of blockchain transactions (e.g., they have to fit in a block). Indeed, every approach proposed in the literature achieves only a much weaker privacy guarantee called  $k$ -anonymity where a transactor is private within a set of  $k$  account holders.  $k$ -anonymity is achieved by *adding*  $k$  accounts to the transaction, which concretely limits the anonymity guarantee to a very small constant (e.g., 64 for QuisQuis and 256 for anonymous Zether), compared to the set of all possible accounts.

In this paper, we propose a completely new approach that does not achieve anonymity by including more accounts in the transaction, but instead makes the transaction itself “smarter”. Our key contribution is to provide a mechanism whereby a compact transaction can be used to *correctly* update *all accounts*. Intuitively, this guarantees that all accounts are equally likely to be the recipients/sender of such a transaction. We, therefore, provide the first protocol that guarantees *full* privacy in account-based cryptocurrencies PriFHEte <sup>1</sup>.

The contribution of this paper is theoretical. Our main objective is to demonstrate that achieving full privacy in account-based cryptocurrency is actually possible. We see our work as opening a door to new possibilities for anonymous account-based cryptocurrencies.

Nonetheless, in this paper, we also discuss PriFHEte’s potential to be developed in practice by leveraging the power of off-chain scalability solutions such as zk rollups.

## 1 Introduction

Account-based cryptocurrencies (e.g., Ethereum[1], Filecoin[2], Ripple[3] etc.) follow the traditional bank model of keeping balances for accounts. In these cryptocurrencies, each public key (account) is associated with a balance, and a payment from public  $PK_A$  to  $PK_B$  of  $x$  coins, results in simply updating the balances of  $PK_A$  and  $PK_B$  by  $-x$  and  $+x$  respectively. In contrast, the Unspent Transaction Outputs (UTXO) Model, used in Bitcoin, is organized around transactions, and a payment is created by referencing a public key from the output of an unspent transaction. Account-based cryptocurrencies offer several advantages over UTXO for transactions. For example, the account model has better memory usage. Users only need to store a single account balance as opposed to several UTXOs that together make up the balance. Similarly regarding, miner storage, miners need to maintain an ever-increasing set of UTXOs to verify transactions. On the other hand, the size of the state in account-based cryptocurrencies increases only when new accounts are added.

*Privacy in Cryptocurrencies.* Privacy in financial transactions has always been deemed important, as people tend to prefer that the amount of money they have and how they use it, remains private.

---

<sup>1</sup> Pronounced like “private” but with an  $f$  in place of the  $v$ . That is, *prifate*.

Traditional banking systems inherently provide privacy by keeping account balances confidential, known only to the bank and the account holder. However, in the case of cryptocurrencies, public verifiability is necessary as transactions are only added to the blockchain if they can be verified by the public. As a result, privacy must be added to cryptocurrencies carefully, without compromising public verifiability. De-anonymization attacks on Bitcoin [36,43] have demonstrated that using randomly generated public keys provides limited privacy, as payments can be traced and, in combination with other metadata, can be used to associate real identities with public keys. This has led to a significant amount of research aimed at adding privacy to cryptocurrencies [37,45,40,20,14,19], with various trade-offs between privacy and efficiency (as discussed in Section 2).

For the UTXO model, it is possible to achieve full privacy while still maintaining efficiency and public verifiability. For example, ZCash [28] is a fully private, publicly verifiable and practical UTXO payment system. The main idea of such systems is to associate a transaction to a serial number and commit to the serial number and the value of the transaction. This commitment is added to a public pool (also referred to as state), succinctly represented by a Merkle Tree. To spend an unspent transaction, the unique serial number is revealed and a succinct zero-knowledge proof is provided to demonstrate that this serial number represents one of the transactions committed to the pool. Then, a new serial number representing the new unspent transaction is committed to the pool. However, the main disadvantage of this approach is that the pool of private transactions grows infinitely. Additionally, the miners must keep track of all the serial numbers that have been revealed over time.

*Privacy in Account-based Cryptocurrencies.* In account-based cryptocurrencies, the state is a list of accounts with their respective balances (e.g.,  $PK_A, v_A$ ) and payment is an *update* of two account balances in this state. The sender’s balance is decreased by  $x$  and the receiver’s balance is increased by  $x$  (for simplicity, miner fees are ignored). As a result, the state of the blockchain can be viewed as a large table with one row per account, and payments require updating two rows in the table. It can be seen that the serial number-based approach used in Zcash would not work in this model, as payments require updating account balances, rather than just burning an unspent transaction.

To add privacy to account-based cryptocurrencies, current solutions, such as QuisQuis [20], Zether [14] and anonymous Zether [19] hide the balance of the users by encrypting or committing to balances using a homomorphic scheme. This achieves confidentiality. To add anonymity they [19,20] rely on the concept of adding multiple accounts to a payment transaction. This way, an external observer cannot determine the pair of accounts executing the transaction. Instead of creating a transaction with only the public keys of the sender and receiver, the sender will select a set of  $k - 2$  other public keys to form a “ring”. A multi-account transaction is then created, containing  $k$  ciphertexts and a zero-knowledge proof that two out of the  $k$  ciphertexts correctly encrypt a balance transfer between two account holders, while the remaining ciphertexts are encryptions of 0. The miner processing this transaction, updates the  $k$  rows in the state, by homomorphically adding each ciphertext to the correct row. This approach provides  $k$ -anonymity to the sender and receiver.

QuisQuis and anonymous Zether suggest using an anonymity set of size 16, while Monero [40,33]<sup>2</sup> suggests a ring size of 11. These values of  $k$  are a very small fraction of the total number of account holders, and provide very fragile guarantees, as shown by the attacks proposed in [38,32] on the traceability of the sender of transactions in Monero. Furthermore, the limitation on the anonymity set is inherent with this technique, since the choice of  $k$  must be upper-bounded by the maximum size of the transactions that can fit in a block. If we consider the typical size of a blockchain block, the maximum anonymity set that an account holder can obtain is around 64 for QuisQuis and 256 for anonymous Zether<sup>3</sup>. Another significant drawback of this approach is that the choice of the accounts that are included in the anonymity set must be done carefully, since a bad choice of accounts

<sup>2</sup> Monero is a UTXO-based cryptocurrency that however uses the *ring* approach to achieve anonymity.

<sup>3</sup> We extrapolated these values from the following data from [19]: for an anonymity set of 16, the size of the transaction for QuisQuis is 26KB, and for anonymous Zether is 6KB, and we consider the maximum blocksize to be 100KB (<https://bitinfocharts.com/comparison/size-eth.html>)

(e.g., accounts that rarely appear in any transaction) can reduce even further the actual anonymity guarantees.

There seems to be a major obstacle to achieving full anonymity in account-based cryptocurrencies. Since anonymity depends on the number of accounts involved in the transaction, full anonymity would require the transaction to be at least as large as the entire table of accounts, which is infeasible to implement.

In this paper we ask the following *feasibility* question:

*Is it possible to achieve full anonymity in account-based blockchains with transactions that are independent of the anonymity set?*

## 1.1 Our contribution

In this paper, we answer the above question positively. We provide a novel approach for creating privacy-preserving transactions that are compact and provide *privacy within the set of all account holders*<sup>4</sup>. Our work provides the strongest anonymity degree with the shortest transaction size, and is asymptotically most efficient for account holders. We prove security in the Universally Composable (UC) [16] model, using the private-ledger functionality introduced by Kerber et al. [30]. To the best of our knowledge, this is also the first account-based privacy-preserving payment protocol that is UC-secure (regardless of the efficiency).

## 1.2 Our Techniques

Recall that our goal is to create payment transactions that have full anonymity w.r.t. all existing account holders, and confidentiality of the amount transferred. To achieve confidentiality, we first encrypt the balances of each account holder under their public key. The transfer transaction includes ciphertexts that are added to the corresponding encrypted balance. However, for a transaction to have full anonymity, it is essential that every account’s ciphertext is updated during the payment transaction processing. If even a single account is not updated, the anonymity set is reduced by one. To solve this challenge, we need to craft two ciphertexts,  $c_S$  and  $c_R$ , that can be homomorphically evaluated with each ciphertext  $c_1, c_2, \dots, c_N$  in such a way that all ciphertexts are correctly updated with the re-encryption of their current balances, while only the ciphertexts of the sender and receiver’s accounts are updated with the new balance.

The main challenge to achieving this is that each every ciphertext is computed under a *different key*. How can two ciphertexts be used to homomorphically update  $N$  ciphertexts computed under  $N$  different keys?

We solve this conundrum by taking inspiration from the recent elegant work by Liu and Tromer [34] that faces a similar challenge for a very different problem (see Section 2). Their work leverages a special property that exists in some LWE-based encryption schemes for plaintexts in  $\{0, 1\}$ , called wrong key decryption (see Def 3). This property states that, *even when a ciphertext is decrypted with the wrong key, the decryption function always returns a bit* (Regev’s encryption scheme [42] and the LWE scheme from PVW [41] satisfy this property).

With this property in hand, our main idea is to use two encryption schemes, a fully homomorphic encryption (FHE) scheme to *encrypt the balance* and an encryption scheme with the property of wrong-key decryption (denoted WKEnc). The encryption scheme WKEnc is used to hide the identities of the sender and receiver. With the wrong-key decryption property, we can (using FHE) homomorphically decrypt<sup>5</sup> a ciphertext, using the encryption of different secret keys. This results in ciphertexts such

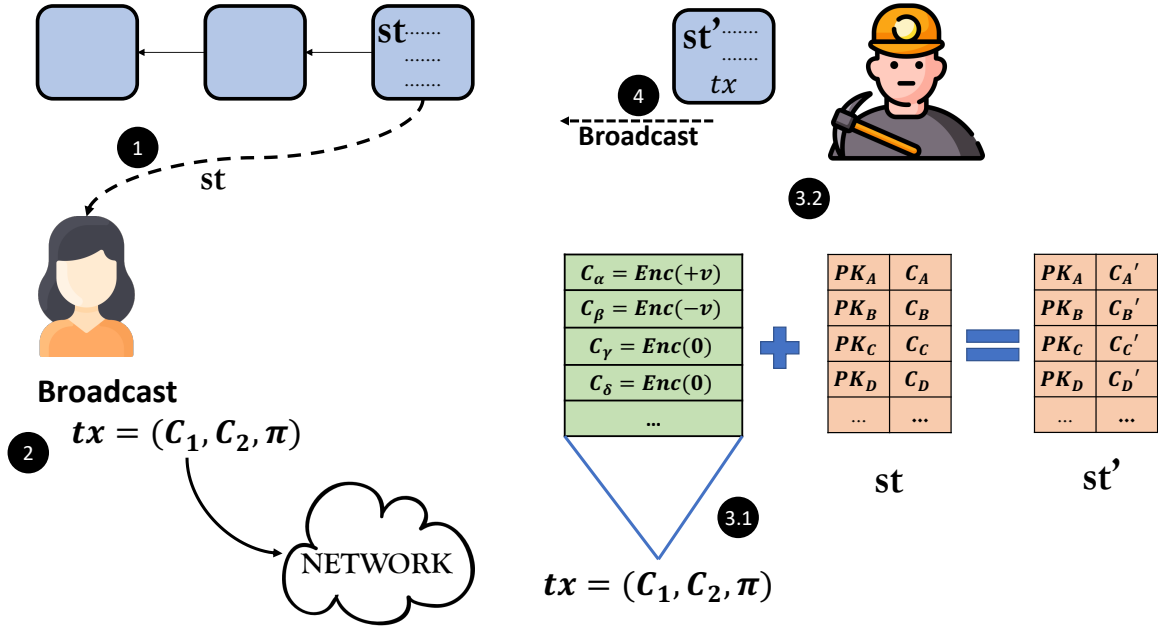

<sup>4</sup> “All account holders” means all account holders that have a private account. If a blockchain does not have privacy by design, then some people could choose to have a public account only. Such accounts, naturally, would not count in the anonymity set.

<sup>5</sup> This is reminiscent of Gentry’s [24] Recrypt operation associated with FHE schemes for bootstrapping.

that only the encryption of the *desired* secret key (of the sender or the receiver) will decrypt the desired result.

This property allows for oblivious selection! When we obliviously decrypt (via FHE evaluations) using the correct keys, i.e., the keys of the sender and the receiver, the oblivious decryption will return encryption of the correct bits; whereas when we attempt to obliviously decrypt using the other keys, the ciphertext resulting from the computation will have at least one wrong bit. We use this observation to compute a flag that can be used to selectively and obliviously update the balance only of the sender and the receiver.

With this intuition in mind, we proceed with a more detailed description of our payment system PriFHEte. We will describe how a user can (1) create a private account, (2) create a private payment, and (3) how the blockchain nodes process a private payment. A visual of our protocol can be found in Fig. 1

**Fig. 1.** Overview: **1** A user with address  $PK_B$  retrieves the latest state commitment - denoted  $st$ . **2** She computes a transaction  $C_1, C_2, \pi$ , where  $\pi$  is proof that proves that the transaction is valid with respect to the current state. This transaction is broadcast to the network. **3.1** A miner processes this transaction and computes  $N$  ciphertexts such that the balance of the sender is decremented by  $v$ , the balance of the receiver is incremented by  $v$  and an encryption of 0 is added to all the other balances thus re-randomizing them. **3.2** The miner then computes the updated state denoted  $st'$  **4** The miner then broadcasts a block with the updated commitment to the state and the transactions.

*Creating a Private Account:* To create a private account, a user  $P_i$  creates two types of keys, a key-pair for an encryption scheme with the wrong-key decryption property (WKEnc):  $(WKEnc.pk_i, WKEnc.sk_i)$ , and a key-pair for a fully homomorphic encryption scheme (FHE):  $(FHE.pk_i, FHE.sk_i)$ . Furthermore,  $P_i$  computes a bit-wise FHE encryption of its WKEnc secret key  $WKEnc.sk_i$  to obtain a vector of  $|WKEnc.sk_i|$  FHE ciphertexts, that we denote by  $k-ct_i$ . Looking ahead, the FHE encryption of its secret key will be used by the miners to *obliviously decrypt* WKEnc ciphertexts, inside the FHE, in order to decide if this public key is the sender or receiver of the payment.  $P_i$  publishes  $PK_i = (WKEnc.pk_i, FHE.pk_i, k-ct_i)$ .

The private balance  $v$  associated to a public key  $\text{PK}_i$  is represented as a bit-wise encryption of  $v$ , using FHE public key  $\text{FHE.pk}_i$ . Namely, if  $v = (v_1, \dots, v_\mu)$ , the private version is  $\mathbf{C}_i = [\text{FHE.Enc}(\text{FHE.pk}_i, v_1), \dots, \text{FHE.Enc}(\text{FHE.pk}_i, v_\mu)]$ .

*The list of accounts:* The table of all accounts consists of  $N$  rows, one for each account holder, where  $N$  can increase dynamically over time as more accounts are created. Each row consists in the tuple:  $[\text{PK}_i; \mathbf{C}_i]$

*Private Payment.* Now, suppose that account holder  $\text{PK}_S$  (the sender) wants to send the amount  $x$  to a receiver  $\text{PK}_R$ . First,  $\text{PK}_S$  will prepare a bit-wise  $\text{WKEnc}$  encryption of the public key of the sender and the receiver of the payment. That is,  $\text{PK}_S$  encrypts the keys  $\text{WKEnc.pk}_S$  and  $\text{WKEnc.pk}_R$ , obtaining vectors of ciphertexts  $\mathbf{C}_S, \mathbf{C}_R$ . Next, the sender  $\text{PK}_S$  creates an  $\text{WKEnc}$  encryption of the bit-wise representation of the amount  $x$  it wishes to transfer to  $\text{PK}_R$ 's account, and another  $\text{WKEnc}$  encryption of the bit-wise representation of the value  $-x$  that should be deducted from  $\text{PK}_S$ 's account. We denote by  $\mathbf{C}_C$  (credit) and  $\mathbf{C}_D$  (debit) the two vectors of ciphertexts. Finally, the sender computes a succinct zero-knowledge proof of knowledge of the secret key associated with the public key  $\text{PK}_S$  used to encrypt the debit  $\mathbf{C}_D$ , that the balance for the account was greater than  $x$  before this transaction, and that all ciphertexts were computed correctly. A private payment thus consists of the tuple:  $(\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \pi)$ .

It is important to note at this point that the proof of correctness  $\pi$  must hold with respect to the *latest version* of the ‘‘table of private accounts’’ (e.g., the most updated version of the blockchain), which is succinctly represented by the root of a Merkle tree. Using the latest version can raise subtle concurrency issues like *front-running transactions* and *double-spending*<sup>6</sup>. We will discuss those issues, and what needs to be added to fix them, after we present an overview of how a miner processes transactions.

*Processing a Private Payment.* Upon receiving the payment  $(\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \pi)$  a miner will obviously update the ciphertext of all account holders as follows. First, recall that each account holder publishes the FHE encryption of its  $\text{WKEnc}$  secret key  $\text{k-ct}_i$ . For each account holder  $\text{PK}_i = (\text{FHE.pk}_i, \text{WKEnc.pk}_i)$  the miner will perform the following five steps.

1. First, it tries to obliviously decrypt the public key hidden in  $\mathbf{C}_S$ , using the secret key encrypted in  $\text{k-ct}_i$ . This is done via FHE, namely by evaluating the circuit of the  $\text{WKEnc}$  decryption function. The result of this operation is FHE ciphertexts of a sequence of  $\lambda$  bits, which is either  $\text{WKEnc.pk}_S$  or is a sequence of  $\lambda$  random bits, let us call it  $pk'$  that differs from  $\text{WKEnc.pk}_S$  for at least one bit<sup>7</sup>. We call this ciphertext  $\mathbf{C}_i^{\text{id}}$ , to denote that this ciphertext could potentially be the encryption of the public key of the sender.
2. Next, we obliviously xor the bit-string encrypted in  $\mathbf{C}_i^{\text{id}}$  with the *negation* of the public key  $\text{WKEnc.pk}_i$ . To see why we do this, notice that if the string from  $\mathbf{C}_i^{\text{id}}$  matches the  $\text{WKEnc.pk}_i$ , then the xor with the negation  $\text{WKEnc.pk}_i$  will result in string of  $\lambda$  1s. On the other hand, if the strings don't match (for all remaining public keys performing this xor) the result will be a string that has both zeros and ones. This vector of ciphertexts is denoted  $\mathbf{C}_i^{\text{preflag}}$ .
3. To nullify the noise, and make sure that even one zero disqualifies this public key, we multiply all the ciphertexts in  $\mathbf{C}_i^{\text{preflag}}$  together. This gives us a flag ciphertext, which we call  $C_i^{\text{flag}}$ , which is an FHE encryption of the bit 1 if  $\text{PK}_i$  is the sender of the payment, and of 0 otherwise.
4. Before the miner can use the flag ciphertext  $C_i^{\text{flag}}$  to update the balance of  $\text{PK}_i$ , i.e., to update the FHE ciphertext  $\mathbf{C}_i$ , the miner must transform the  $\text{WKEnc}$  ciphertext of the amount  $-x$ ,  $\mathbf{C}_D$ , into an FHE ciphertext encrypted under the same key. This is easily done as above where the circuit of  $\text{WKEnc}$  decryption function is evaluated on  $\mathbf{C}_D$  to get a new ciphertext  $\mathbf{C}_i^{\text{x}}$ .
5. Now we can finally leverage our flag ciphertext  $C_i^{\text{flag}}$  and perform a bit-wise multiplication with  $\mathbf{C}_i^{\text{x}}$  to obtain an encryption of the value we need to add to the balance  $\mathbf{C}_i$  or simply an encryption of 0.

<sup>6</sup> These issues were already outlined Zether [14].

<sup>7</sup> If it was not the case, this means that we are able to correctly decrypt using the wrong key, which would break the CPA-security of the encryption scheme.

6. The final step is to add  $\mathbf{C}_i^x$  to the current balance ciphertext for  $P_i$ , and this will complete the update for the debit ciphertext. The same process is then repeated for the credit ciphertext  $\mathbf{C}_C$ .

For the convenience of the reader, in Appendix A we additionally provide a pictorial representation of all the operations involved in updating the state.

*Dealing with Concurrency Issues.* As explained above, a payment consists of the tuple  $(\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \pi)$ , where the proof  $\pi$  asserts that the payer is the owner of the sender’s account, and the encrypted balance associated to their account has enough funds to perform the transfer and that the ciphertexts were computed correctly. This proof is computed over the newest version of the table of accounts  $\mathcal{T}$  succinctly described by the Merkle Root  $rt_{\mathcal{T}}$ . Now, say that  $rt_{\mathcal{T}}$  is the most updated version of the table at time  $t$ . All payments that are crafted from time  $t$  to  $t + 1$  will have  $rt_{\mathcal{T}}$ , as a reference of the table of accounts, and as a theorem for the proof  $\pi$ . We will now describe the two concurrency-related issues - double spending and front-running and the mechanisms we use to fix them.

*Avoiding Double spending :* A malicious account holder could craft multiple payments from its account in the interval  $[t, t + 1]$  referring to the same root  $rt_{\mathcal{T}}$ . In other words, say that an account holder holds a public key  $pk_i$  which has a balance of 5 Eth in  $rt_{\mathcal{T}}$ . In the interval  $[t, t + 1]$ ,  $pk_i$  can create multiple payments for up to 5 Eth and correctly compute the ZK proof  $\pi$  since it is connected to a state  $rt_{\mathcal{T}}$  where  $pk_i$  still owns 5 Eth. All these transactions will be considered valid, and since our transactions are fully anonymous, a miner cannot determine if two transactions originated from the same sender. To address this issue of double-spending, we enforce that each account holder can speak at most once per epoch ( $\eta$  consecutive slots) We achieve this by employing a pseudorandom function (PRF) (a similar approach is used in the anonymous version of Zether [14], where each transaction includes  $g^{sk}$ , where  $g$  is a public random nonce that is announced at the beginning of each epoch). In our construction, the account holder commits to the PRF key during setup. The account holder then must attach the deterministic output of the PRF evaluated on the epoch number to each transaction, we denote this value by PRFOut. Since the output of the PRF is deterministic, this prevents the account holder to generate two distinct payments for the same epoch. In the proof, we use the zk property of the NIZK to prove that it knows the opening to a commitment of the PRF key and thus maintains anonymity.

*Defenses Against Front-running:* Suppose Alice creates an honest transaction in the interval  $[t, t + 1]$ , but the transaction is picked up by a miner at time  $t + 2$ , by which time the state of the blockchain, and thus Alice’s ciphertext and the root would have been updated. This would trivially invalidate Alice’s proof without any malicious behavior from other parties. We mitigate this front-running problem by allowing an account holder to create a transaction with respect to any of the states in an epoch. This ensures that even if the state has changed, the transaction would be considered valid with respect to one of the previous states in the epoch.

*Compactness of our transactions.* In our private transactions  $tx = [\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$  The number of ciphertexts in  $\mathbf{C}_S, \mathbf{C}_R$  is  $\lambda$  each, and the number of ciphertexts in  $\mathbf{C}_D, \mathbf{C}_C$  is  $\mu$ , where  $\mu$  is the number of bits in the maximum possible value that can be transferred. Thus a transaction consists of  $2\lambda + 2\mu$  ciphertexts, which is independent of the number of users, and a proof  $\pi$ . One can instantiate  $\pi$ , with constant size SNARKs [26,22]. Since we use the Universal Composability framework to prove security, we require that the SNARKs be UC-secure. Work by Kosba et. al. [31] describes how to construct SNARKs with proof size proportional to the size of the witness. This makes our proof size  $O(\log N)$  since the witness includes a Merkle path. More recently, succinct UC-secure NIZKs were proposed in the Global Random Oracle Model[23], where the proof size is constant.

*Security of Our Protocol.* We prove the security of our protocol in the UC model. There exist multiple definitions of a private ledger functionality [30,25]. We prove security by instantiating the Private Ledger functionality introduced in [30]. Note that the Private Ledger functionality captures both the ledger properties (i.e., the underlying consensus protocol) as well as the privacy properties required of the transactions. Since, in this paper, we are providing an account-based payment system on top

of any existing ledger, our proof of security will cover only part of the functionality concerning the submission and handling of private transactions.

Furthermore, since the UC specification is often more complex (as it has additional language that is part of the model), for ease of reading, we have provided two descriptions of our protocol. In Section 4, we provide a bare-bones description of the procedures of our protocol (e.g., key registration, mint, transfer, etc), and their implementation. Then in Section 5 we show how the procedures described in Section 4 can be used to instantiate the Private Ledger functionality.

### 1.3 The significance of this work

The goal of this work is to demonstrate *feasibility* of achieving full anonymity in account-based cryptocurrency. Our key idea has been to enable a global state update (i.e., the entire state is updated per transaction) with a constant number of ciphertexts, by leveraging the power of Fully Homomorphic Encryption.

Our reliance on FHE, however, makes our protocol unlikely to be deployable in practice soon. This naturally raises the question: is a heavy tool such as FHE necessary for the account-based setting and if so, what is the significance of this work for account-based cryptocurrencies?

We do not have a definite answer to this question, but in this paragraph, we will discuss several ideas to contribute to the answer from different angles.

We start with observing that the problem of achieving full privacy in account-based cryptocurrencies in a blockchain environment where a miner works independently, can be abstracted as the problem of anonymously updating an encrypted database containing data from multiple clients (accounts) that is stored on an untrusted server. The miner is the untrusted server, the account-balance table is the database, and the transaction is the message that a party must send to the server in order to anonymously update their entry. Under the assumption that clients do not talk to each other, and there is a single, untrusted server, this problem resembles the problem of server-aided MPC with a single server. For such a problem, the only known solutions are based on Multi-key FHE[35,5] (such works actually require that clients (account holders) interact with each other even if FHE is used).

Hence, if we stick with the standard blockchain setting where miners work independently and are mutually distrustful it seems that using a powerful tool such as FHE is necessary.

On the other hand, if we allow interactions between miners, or participating of external servers or clients, we could hope for more efficient solutions based on garbled circuits [11]. This direction however does not seem too promising in the blockchain world, where public verifiability is a necessary requirement.

However, we would like to conclude on a positive note, suggesting a completely different approach that could solve the problem at the root – by reducing the state. Indeed, in our previous argument, we were making the assumption that the miners keep the entire state and each party only holds their own secret.

However, in recent years, a different approach has been developed that shifts the work from the miner to the clients, called *stateless cryptocurrencies* (Agrawal et al. [4] and Tomescu et al. [47].) Instead of having the miner update the state upon each transaction, it has the clients update their secrets upon each transaction that is uploaded on the blockchain (that is, even transactions that do not involve the client’s balances). The key advantage of such a shift is that it allows a miner to correctly verify the soundness of a state update without having to know the entire state, making the miners’ computation very fast and the storage minimal, at the price of having clients making continuous updates to their local state. This is an interesting approach that can potentially allow anonymous updates without heavy machinery. We leave exploring this direction to future work.

## 1.4 Potential for Deployment

While we acknowledge that PriFHEte requires miners to perform heavy computation and is unlikely to be practical soon, we also would like to discuss avenues for practical deployment that stem from leveraging the power of smart contracts.

*Generality of our PriFHEte.* An important feature of our protocol is that it is not tied to any blockchain. Our functions can be executed as a smart contract on top of any account-based blockchain that supports smart contracts and does not require any change to the underlying rules of the blockchain. Users create and submit transactions as described above and miners simply execute the smart contract which runs the function to process transactions and update an internally maintained state. We discuss this in more detail in Appendix G. (This is in contrast with solutions for UTXO-based cryptocurrencies that require a significant change in design and resulted in the creation of separate cryptocurrencies, such as Zcash [45], Monero).

*Delegating Miner’s Computation.* Since PriFHEte can be described as smart contracts that run on the blockchain, the heavy computations that miners must do when dealing with a PriFHEte’s smart contract could be delegated to external servers, by leveraging an emerging technology called zk-rollups [21] (currently available in the Ethereum ecosystem). A zk-rollup is an external server, called rollup operator that maintains the state and executes smart contracts on behalf of the miners. Miners only maintain a succinct representation of this state, typically a Merkle tree root. This aids the storage costs borne by the miner. Users submit their transactions to the rollup operator instead of the blockchain miners. The operator updates the state and broadcasts an updated succinct state, the transactions, and a validity proof proving that the state was updated correctly. A miner now only has to verify this proof and accepts the new succinct state. This aids the heavy computation that needs to be undertaken by the miner. We discuss deployment with rollups in more detail in Appendix G.

Finally, we conclude with a discussion about user’s efficiency. Recall that, to craft a payment transaction, the account holder must hold the newest version of her own ciphertext, as well as the most updated version of the Merkle Tree of the entire table of accounts. Since all payments are made public, any user can perform the same computation of the miners for staying updated with the latest state. All previous work [20,14] implicitly make the assumption that users will stay updated. In practice, however, it is important to reduce the burden of the computation on the client. Light clients [17] can be used to have the account holder to reliably obtain the information it needs from a blockchain node instead. The question on how/when to ask for this information is as important for guaranteeing anonymity w.r.t. the miners, since asking for the root only when preparing a payment can reveal the network identity of the asker. This question is orthogonal to our work and several existing approaches can be used to address it [50,49] hence we do not discuss it further.

## 1.5 Roadmap

The rest of the paper is organized as follows. Section 2 presents other works that achieve privacy-preserving payments on public ledgers. We present our main cryptographic building blocks in Section 3. We then present our main algorithms that are run by the parties in Section 4. Section 5 presents a UC specification of the protocol  $\Pi_{\text{PriFHEte}}$  that makes use of the algorithms presented in Section 4. We sketch a proof overview in Section 6 that realize the  $\mathcal{G}_{\text{PL}}$  functionality (presented in Appendix B) and the full proofs are presented in Appendix D.

## 2 Related Work

**Privacy-preserving payments in the account-based model.** Fauzi et al. [20] present QuisQuis where the account is represented as a tuple of public key and a commitment to the balance. To create a transaction, the sender selects a list of valid accounts (that contribute to the anonymity set) and

updates these decoy accounts (by re-randomizing them) and the accounts involved in the transaction (by transferring value). Since an adversary cannot learn which accounts were updated with some value, their protocol achieves  $k$ -anonymity. Note that the size of the transaction increases with the anonymity guarantee provided. Also, each transaction updates the accounts of the users, and these users are expected to post `DestroyAcct` to keep the size of the state constant. As observed in [19], since the parties are not incentivized to destroy their old accounts it is unclear if the state of the system is constant. Bünz et al. [14] present Zether that builds on the same idea as above, except that the balances are stored using ElGamal encryptions. They only achieve confidentiality and not anonymity, therefore each transaction only includes two ciphertexts. In their appendix, they sketch an approach to achieve  $k$ -anonymity and this idea was formally analyzed and made more efficient by Diamond [19]. But this protocol also only achieves  $k$ -anonymity. In contrast, in our work, we are able to achieve full privacy in the same setting with only  $O(\log N)$  sized transactions.

**Privacy-preserving payments in UTXO-model.** Techniques for privacy-enhancing payments in the UTXO require miners to maintain commitments of values as well as the serial numbers of spent coins. Since every transaction in the UTXO model leads to creation of new coins, the state of the system (consisting of the commitments and the serial numbers) is always increasing. There are mainly two approaches: 1) ones that achieve full privacy - Zerocoin[37], Zerocash[45], [39] which use zk-snarks[22] and 2) ones that achieve a weaker form of anonymity ( $k$ -anonymity) - Monero [40] which use ring signatures.

Our solution does not increase the state of the system with every transaction. The state increases only when a new account joins the system.

**Privacy-preserving payments in the account-based model that use UTXOs.** Another popular approach to achieve anonymity in the account-based setting is by having users convert funds in their account to private coins and spend these coins in a privacy-preserving way similar to the UTXO setting. This may be deployed as a smart contract as is the case in Zeth [44], AZTEC [48] or standalone - Veksel [15], BlockMaze [27]. These protocols provide varying guarantees of anonymity. Zeth [44] achieves only receiver anonymity. The sender is not anonymous, since they need to pay gas fees from a public account to execute the smart contract. In Section 4.3 we show how we get around this issue by converting private funds to public gas fees. BlockMaze [27] and Veksel [15], do not achieve any anonymity. They only guarantee that a sender of a transaction cannot be linked to the recipient of the transaction. In these works, the sender submits a transaction publicly linking the transaction to the sender. At a later point in time, the receiver rerandomizes the transaction and transfers the funds in the transaction to its own account. The re-randomization unlinks the sender from the receiver, but they do not hide the sender and the receiver identities. In Aztec [48], only the recipient of a transaction is anonymous. The coins encrypting transaction values are denoted as notes. A public note registry keeps track of the unspent notes, which are updated upon processing a new transaction. That is, the input notes are removed from the registry and the output notes are added to the registry. Since this leaks information on the sender and receiver of a transaction, AZTEC proposes to use one-time addresses (stealth addresses) for the receiver. This successfully unlinks the identity of the sender from the identity of the receiver. But we note that stealth addresses allow the sender to track when the receiver spends the funds. Finally, Espresso systems [46] achieve anonymity for the sender (except to a trusted relayer) and the receiver. They present a smart contract that enables Zerocash-like transactions on the Ethereum blockchain. This ensures privacy to the sender and the receiver. Moreover, they sidestep the issue of de-anonymization of the sender via gas fees by making use of a special party, denoted the Relayer that submits the transaction to the blockchain. This presents an additional weak layer of privacy, since the sender of the transaction is now hidden (except to the relayer). Our work on the other hand achieves full anonymity for the recipient and sender.

Besides these weaker anonymity guarantees, as noted in Zether [14], this hybrid approach has several disadvantages based on committed coins. First, storage costs are very expensive in account-based blockchains such as Ethereum, and since the state is always increasing the coin-based solution

will be very expensive. Second, using coins creates friction when trying to operate with smart contracts. Finally, in this hybrid approach users now need to keep track of all their unspent coins, instead of maintaining just the secret key of their account. Our work achieves full anonymity and retains many of the benefits of the account-based approach (e.g., the state does not grow, the user does not need to remember all the private coins she possesses, but only needs to remember her secret key).

### 3 Preliminaries

#### 3.1 Fully Homomorphic Encryption

We follow the definition of FHE presented in [13]. We use  $\lambda$  as the security parameter and all schemes in this paper encrypt bit-by-bit. A fully homomorphic encryption scheme  $\text{FHE} = (\text{FHE.KeyGen}, \text{FHE.Enc}, \text{FHE.Eval})$  is a quadruple of PPT algorithms as follows.

- **Key Generation.** The algorithm  $(\text{pk}, \text{sk}) \leftarrow \text{FHE.KeyGen}(1^\lambda)$  takes as input the security parameter and outputs a public encryption key  $\text{pk}$ , and a secret decryption key  $\text{sk}$ . Unlike [13] we treat the evaluation key  $\text{evk}$  as part of the public key  $\text{pk}$ .
- **Encryption.** The algorithm  $c \leftarrow \text{FHE.Enc}(\text{pk}, m)$  takes the public key  $\text{pk}$  and a single bit message  $m \in \{0, 1\}$  and a secret decryption key  $\text{sk}$ .
- **Decryption.** The algorithm  $m \leftarrow \text{FHE.Dec}(\text{sk}, c)$  takes the secret key  $\text{sk}$  and a ciphertext  $c$  and outputs a message  $m \in \{0, 1\}$ .
- **Homomorphic evaluation.** The algorithm  $c_f \leftarrow \text{FHE.Eval}(\text{pk}, f, (c_1, \dots, c_\ell))$  takes the public key  $\text{pk}$ , a function  $f : \{0, 1\}^\ell \rightarrow \{0, 1\}$  and a set of  $\ell$  ciphertexts  $c_1, \dots, c_\ell$  and outputs a ciphertext  $c_f$ .

The security notion we consider is IND-CPA security defined as follows.

**Definition 1.** (*CPA security*). A scheme  $\text{FHE}$  is IND-CPA secure if for any polynomial time adversary  $\mathcal{A}$  it holds that

$$\text{Adv}_{\text{CPA}}[\mathcal{A}] = |\Pr[\mathcal{A}(\text{pk}, \text{FHE.Enc}(\text{pk}, 0)) = 1] - \Pr[\mathcal{A}(\text{pk}, \text{FHE.Enc}(\text{pk}, 1)) = 1]| = \text{negl}(\lambda)$$

#### 3.2 Key-Private Public Key encryption with wrong-key decryption

Our constructions use a CPA secure encryption scheme with certain special properties namely that of key-privacy (Def 2) and wrong-key decryption (Def 3). We denote this encryption scheme in the description of our protocols as  $(\text{WKEnc.KeyGen}, \text{WKEnc.Enc}, \text{WKEnc.Dec})$ . Wrong-key decryption informally states that a ciphertext decrypted with the wrong secret key will always return a valid plaintext and return the correct plaintext only with some negligible advantage ( $\frac{1}{2} + \text{negl}$ ). As noted in [34] all the above properties are satisfied by LWE encryption scheme of Regev [42] and Peikert et al [41]. We present Regev’s scheme and a sketch of why Regev’s scheme gives a wrong-key decryption property in Appendix E.

We present the notion of key-privacy under chosen plaintext attacks as defined in [10] and the wrong key decryption defined in [34]:

**Definition 2.** (*Key privacy*) A scheme  $\text{WKEnc}$  is IK-CPA secure if for any polynomial time adversary  $\mathcal{A}$  it holds that

$$\begin{aligned} \text{Adv}_{\text{IK-CPA}}[\mathcal{A}] &= |\Pr[\mathcal{A}(\text{pk}_0, \text{pk}_1, x, \text{WKEnc.Enc}(\text{pk}_0, x)) = 1] \\ &\quad - \Pr[\mathcal{A}(\text{pk}_0, \text{pk}_1, \text{WKEnc.Enc}(\text{pk}_1, x)) = 1]| = \text{negl}(\lambda) \end{aligned}$$

**Definition 3.** (*Wrong-key Decryption*) For an encryption scheme with plaintext space  $\mathbb{Z}_2$  letting  $(\text{sk}, \text{pk}) \leftarrow \text{WKEnc.KeyGen}(1^\lambda)$  and  $(\text{sk}', \text{pk}') \leftarrow \text{WKEnc.KeyGen}(1^\lambda)$ ,  $\text{ct} \leftarrow \text{WKEnc.Enc}(\text{pk}, 1)$ , and  $m' \leftarrow \text{WKEnc.Dec}(\text{sk}', \text{ct})$ , it holds that

$$\Pr[m' = 1] \leq 1/2 + \text{negl}(\lambda)$$

### 3.3 Pseudorandom functions with unpredictability under malicious key generation

In our construction, we use a pseudorandom function PRF with an additional property of unpredictability under malicious key generation. The definition for a PRF is that for all PPT distinguishers  $D$ , there exist a negligible function  $\text{negl}$  such that  $\Pr[D^{\text{PRF}(k,\cdot)}(1^\lambda) = 1] - \Pr[D^{f(\cdot)}(1^\lambda) = 1] \leq \text{negl}(\lambda)$ , where  $f$  is a truly random function.

Informally, unpredictability under malicious key generation (introduced in [18]) requires that the function PRF does not have any "bad" keys that an adversary can use to manipulate the output of the PRF.

In the random oracle model, the property can be expressed as follows: For any PPT adversary  $\mathcal{A}$  and  $x \in X, T \in \mathbb{N}$ , the probability of the event  $\Pr[\text{PRF}(k, x) = T | x \notin Q_H] = \frac{1}{2^x}$ , where the adversary outputs  $k$  and  $Q_H$  is the set of queries of  $\mathcal{A}$  to the hash function  $H$ . The construction presented in Crypsinous[30] is  $H(m)^k$ . By the DDH assumption, this is a secure PRF. Regarding unpredictability, observe that  $\Pr[H(x)^k = T] = \Pr[H(x) = T^{1/k} = 1/2^\lambda]$  in the conditional space that  $x \notin Q_H$ .

### 3.4 Non-interactive zero knowledge

We use the  $\mathcal{F}_{\text{nizk}}$  functionality to compute and verify zero-knowledge proofs. We present the ideal functionality in Appendix C (Fig 25). The functionality provides an interface for parties to create proofs  $\pi$  that a statement  $x$  is in a given NP language  $\mathcal{L}$  with a witness  $w$ . Moreover, as proven in [30] the  $\mathcal{F}_{\text{nizk}}$  functionality can be realized by the SNARK proving system described in [31].

### 3.5 Blockchain

A blockchain is an ever-growing hashchain of blocks. Each block consists of transactions and this hashchain is agreed upon by a dynamic set of nodes, often referred to as miners. Each user in the network may have a different version of the blockchain (denoted  $\mathcal{C}_{\text{loc}}^i$  for user  $P_i$ ), constrained by the fact that each  $\mathcal{C}_{\text{loc}}^i$  has a common prefix.

Blockchains generally consist of two kinds of parties *miners* and *users*. The users compute and submit transactions to the network. The miners collect these transactions, validate them and create a block including the valid transactions. A miner then broadcasts the newly created block, thus extending the blockchain. The algorithms used to create and submit transactions are referred to as transaction layer algorithms and the ones used to create and broadcast blocks are referred to as consensus layer algorithms. To set some notation, each block is associated with a slot number  $sl_j$ , where a slot is unit of time. A set of adjacent  $\eta$  slots is called an epoch  $ep$ .

In account-based cryptocurrencies (the setting we consider in this work), a transaction consists of three values: the sender's identity, the receiver's identity and the value to be spent. The miners maintain a list of accounts where each element in the list is a (public key, balance) pair. This list is referred to as the *state* of the blockchain. To validate the transaction, the miner checks that the sender of the transaction is not trying to spend more than their balance. If the transaction is valid, the miner then updates the state by deducting the value of the transaction from the sender's balance and adds the same value to the receiver's balance. We denote the state of the cryptocurrency as  $\mathcal{T}$ . The miners compute a Merkle tree with the elements of  $\mathcal{T}$  as the leaf. The root of this Merkle tree (denoted as  $\text{rt}_{\mathcal{T}}$ ) is also added to every block along with the valid transactions that caused the update to the state.

In a privacy-preserving cryptocurrency, we aim to hide the following information included in a payment: the sender's and receiver's identities and the value to be transferred. The universal composable (UC) framework [16] is a model used to define security properties of complex protocols in a modular way. A definition for an ideal ledger functionality was presented by Badertscher et. al. [8] denoted  $\mathcal{G}_{\text{LEDGER}}$ . Kerber et. al. [30] presented a private version of the ledger functionality denoted  $\mathcal{G}_{\text{PL}}$  (PL stands for private ledger). The properties of hiding the information in a payment transaction as well as other security properties required of a blockchain is captured by the  $\mathcal{G}_{\text{PL}}$  functionality. We give an overview of this functionality in Section 5 and present the complete functionality in Figure 16.

To ease the presentation, we will denote the state of the blockchain  $\mathcal{T}$  as  $\mathcal{T}_{\text{privAccounts}} \parallel \mathcal{T}_{\text{pubAccounts}}$  and  $\text{rt}_{\mathcal{T}} = H(\text{rt}_{\mathcal{T}_{\text{privAccounts}}} \parallel \text{rt}_{\mathcal{T}_{\text{pubAccounts}}})$ . Row  $i$  in  $\mathcal{T}_{\text{pubAccounts}}$  is of the form  $(\text{PK}_i^{\text{pub}}, v_i)$ , where  $\text{PK}_i^{\text{pub}}$  is the account-holder's public key that is associated with their non-anonymous balance. The account-holder uses the corresponding secret key  $\text{SK}_i^{\text{pub}}$  to spend their public balance. Moreover  $\mathcal{T}_{\text{privAccounts}}$  includes elements of the form  $(\text{PK}_i, C_i)$  where  $C_i$  is the encrypted balance and  $\text{PK}_i$  is the public key associated with the account. As above, the account-holder uses the corresponding  $\text{SK}_i$  to spend an their private balance.

## 4 The PriFHEte payment system

In this section we present algorithms for the PriFHEte payment system. We first present the interface in Section 4.1 and then instantiate the algorithms in Section 4.2. In Section 5 we will describe how these algorithms will be used to construct an anonymous account-based cryptocurrency protocol.

### 4.1 Interface for the PriFHEte payment system

*Notation.* We denote by  $P_i$  an account holder. We denote the total number of accounts in the system by  $\text{NumAccounts}$ . Miners (denoted  $Q_j$ ) are account holders that additionally update the state. The state maintained by  $Q_j$  will be denoted as  $\mathcal{T}^j = (\mathcal{T}_{\text{privAccounts}}^j \parallel \mathcal{T}_{\text{pubAccounts}}^j)$ . We assume that the parties already have public accounts in the system. Our privacy-preserving payment scheme  $\Pi_{\text{PriFHEte}}$  is a tuple of polynomial-time algorithms: (**KEYGENERATION**, **REGISTRATION**, **MINT**, **TRANSFER**, **PROCESS TRANSACTION**).

**Key Generation.** The algorithm **KEYGENERATION** creates public key and secret key pairs for an account holder.

**KEYGENERATION** $(\lambda) \rightarrow (\text{PK}, \text{SK})$ : A user  $P_i$  runs **KEYGENERATION** and publishes the public key  $\text{PK}_i$ , while the  $\text{SK}_i$  is used to spend the funds that are sent to the account represented by  $\text{PK}_i$ .

**Account registration.** The algorithm **REGISTRATION** is run by the miner to register the public key for an account. This algorithm updates the state of the blockchain after initializing the account.

**REGISTRATION** $(\text{PK}, \mathcal{T}_{\text{privAccounts}}) \rightarrow \mathcal{T}'_{\text{privAccounts}}$ : A miner  $Q$  runs **REGISTRATION** by adding an entry for user with public key  $\text{PK}$  to the state  $\mathcal{T}_{\text{privAccounts}}$ .

**Minting private funds.** The algorithm **MINT** lets an account-holder transfer funds from a public account to a private account.

**MINT** $(\text{PK}_i, \text{PK}_i^{\text{pub}}, \text{SK}_i^{\text{pub}}, x, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}}) \rightarrow (\text{tx}_{\text{MINT}}, \sigma)$ : A user  $P_i$  executes the **MINT** algorithm to produce a transaction that transfers a value  $x$  from the public state to the private state. This algorithm takes as inputs the public key associated to the private account  $\text{PK}_i$ , the public and secret keys associated to the public account  $\text{PK}_i^{\text{pub}}, \text{SK}_i^{\text{pub}}$ , the public value  $x$  to be transferred to the private account and the root of the public state of the blockchain  $\text{rt}_{\mathcal{T}_{\text{pubAccounts}}}$ . The algorithm outputs a transaction  $\text{tx}_{\text{MINT}}$  and a signature  $\sigma$  on this transaction.

**Transferring private funds.** The algorithm **TRANSFER** allows an account-holder  $\text{PK}_S$  to transfer private funds to an account associated with  $\text{PK}_R$ .

**TRANSFER** $(\text{PK}_S, \text{SK}_S, \text{PK}_R, x, ep, R, \mathcal{C}_{\text{loc}}^S, \text{path}_i, \mathbf{C}_i) \rightarrow \text{tx}_{\text{TRANSFER}}$ : The **TRANSFER** algorithm takes as input the sender's account  $\text{PK}_S$ , the secret key  $\text{SK}_S$ , the receiver's account  $\text{PK}_R$  and the value to be transferred  $x$ . The algorithm also takes as input the sender's local version of the blockchain  $\mathcal{C}_{\text{loc}}^S$ , the current epoch number  $ep$ , the epoch size  $\eta$  and the entry associated with  $\text{PK}_S$  in  $\mathcal{T}_{\text{privAccounts}}$ , denoted  $\mathbf{C}_i$  and the Merkle path from  $\mathbf{C}_i$  to  $\text{rt}_{\mathcal{T}_{\text{privAccounts}}}$  - denoted  $\text{path}_i$ . The algorithm outputs a transfer transaction  $\text{tx}_{\text{TRANSFER}}$

**Verifying transactions and updating state.** The algorithm `PROCESSTRANSACTION` run by a miner  $Q_j$  first verifies transactions and then updates the state of the blockchain with valid transactions.  $\text{PROCESSTRANSACTION}(\text{tx}, \mathcal{T}^j) \rightarrow (\mathcal{T}^j)$ : A miner  $Q_j$  updates the state  $\mathcal{T}^j = \mathcal{T}_{\text{pubAccounts}}^j \parallel \mathcal{T}_{\text{privAccounts}}^j$  of the blockchain, by taking as input the current state  $\mathcal{T}^j$  and a transaction  $\text{tx}$ .

## 4.2 Instantiating PriFHEte

We use the following cryptographic building blocks to implement the above described algorithms:

1. A fully homomorphic encryption scheme - (FHE.Enc, FHE.Dec, FHE.Eval). This may be implemented by existing FHE schemes such as the BGV scheme [12].
2. A key-private encryption scheme for bits with the the additional property of wrong key decryption (see Def. 3) which means that even when the ciphertext is decrypted with a wrong key the resultant plaintext is a random valid bit. Such an encryption scheme can be instantiated with PVW LWE-based encryption scheme [41].
3. A pseudorandom function PRF that is unpredictable under malicious key generation [30] with key  $k$
4. A commitment scheme (Com, Verify).
5. An ideal functionality  $\mathcal{F}_{\text{nikz}}$  that allows users to prove statements for a relation  $\mathcal{R}$  (described in Figure 6).
6. A digital signature scheme (KeyGen, Sign, Verify).
7. A collision resistant hash function  $\mathcal{H}$ .

KEYGENERATION( $\lambda$ ): User  $P_i$  does:

1. Generating keys:
  - $(\text{FHE.pk}_i, \text{FHE.sk}_i) \leftarrow \text{FHE.KeyGen}(1^\lambda)$
  - $(\text{WKEnc.pk}_i, \text{WKEnc.sk}_i) \leftarrow \text{WKEnc.KeyGen}(1^\lambda)$
  - $(\text{sk}_i, \text{vk}_i) \leftarrow \text{Sign.KeyGen}(1^\lambda)$
  - $k \leftarrow \text{PRF.KeyGen}(1^\lambda)$
2. Encrypting WKEnc keys:
  - $\text{k-ct}_i \leftarrow \{\text{FHE.Enc}(\text{FHE.pk}_i, \text{WKEnc.sk}_i[j])\}_{j=1}^{|\text{WKEnc.sk}_i|}$
3. Committing to the PRF key:
  - $\text{C}_{\text{PRF}} \leftarrow \text{Com}(k; r)$  where  $r \leftarrow \{0, 1\}^\lambda$
4. Compute a zero knowledge proof that the keys were generated correctly:
  - Let  $x := \text{FHE.pk}_i, \text{WKEnc.pk}_i, \text{k-ct}_i$
  - Let  $w := \text{FHE.sk}_i, \text{WKEnc.sk}_i$
  - Send (Prove, sid,  $x, w$ ) to  $\mathcal{F}_{\text{nikz}}$  to prove that  $(x, w)$  satisfies relation  $\mathcal{R}_{\text{TRANSFER}}$  (Fig 3) and receive  $\pi_{\text{KEYGEN}}$ .
5. Return  $\text{PK}_i := (\text{k-ct}_i, \text{FHE.pk}_i, \text{WKEnc.pk}_i, \text{vk}_i, \text{C}_{\text{PRF}})$ ,  $\text{SK}_i = (\text{FHE.sk}_i, \text{WKEnc.sk}_i, \text{sk}_i, k)$  and  $\pi_{\text{KEYGEN}}$

REGISTRATION( $\text{PK}_i, \mathcal{T}_{\text{privAccounts}}^j$ ): The miner  $Q_j$  upon receiving  $\text{PK}_i$ :

1. Parse  $\text{PK}_i$  as  $(\text{k-ct}_i, \text{FHE.pk}_i, \text{vk}_i, \text{WKEnc.pk}_i, \text{C}_{\text{PRF}})$
2. For  $j \in [\lambda]$  compute  $C_{i,j} \leftarrow \text{FHE.Enc}(\text{FHE.pk}_i, 0)$ .
3. Set  $\mathbf{C}_i := (C_{i,1}, \dots, C_{i,\lambda})$
4. Update  $\mathcal{T}_{\text{privAccounts}}^j := \mathcal{T}_{\text{privAccounts}}^j \cup \{(\text{PK}_i, \mathbf{C}_i)\}$
5. Output  $\mathcal{T}_{\text{privAccounts}}^j$ .

**Fig. 2.** Joining the system

*Public Parameters.* A list of public parameters is available to all users in the system. These are generated at the “start of time”. The parameters are:  $\eta$  which denotes the size of each epoch  $ep$ , a trusted set up (such as CRS) for the non-interactive zero knowledge proofs. Each block corresponds to a slot number denoted  $sl$ . After every  $\eta$  number of slots, the epoch number is incremented. We now give an overview of the algorithms that we described earlier.

**Joining the system** (Fig 2) To join the system a party  $P_i$  first runs the **KEYGENERATION** algorithm which generates keys for the fully homomorphic scheme FHE, the encryption scheme WKEnc, a signature scheme and a pseudorandom function.  $P_i$  then encrypts each bit of the WKEnc.sk $_i$  using the FHE public key FHE.pk $_i$  to obtain a vector of ciphertexts k-ct $_i$  and computes a commitment to this key denoted as C<sub>PRF</sub>.  $P_i$  then announces its public keys : (FHE.pk $_i$ , WKEnc.pk $_i$ , k-ct $_i$ , C<sub>PRF</sub>) and a zero-knowledge proof that the keys were generated correctly:  $\pi_{\text{KEYGEN}}$ . A miner  $Q_j$  registers the party by running the **REGISTRATION** algorithm where they create an entry for  $P_i$  in table  $\mathcal{T}_{\text{privAccounts}}^j$ . The entry is indexed by the public key PK $_i$  and is initialized with a vector of ciphertexts - that encrypt to 0 under FHE.pk $_i$ . These ciphertexts represent the binary decomposition of the *private* balance of  $P_i$ .

Statement:  $x := \text{FHE.pk}_i, \text{WKEnc.pk}_i, \text{k-ct}_i$ , Witness:  $w := \text{FHE.sk}_i, \text{WKEnc.sk}_i$ , Relation  $\mathcal{R}_{\text{KEYGEN}}$ :

1. k-ct $_i$  is the encryption of the bit-representation of the secret key WKEnc.sk $_i$  under the FHE public key.

$$\text{k-ct}_i = \{\text{FHE.Enc}(\text{FHE.pk}_i, b_j)\} \text{ such that } \sum_{j=0}^{\lambda} b_j \times 2^j = \text{WKEnc.sk}_i$$

2. WKEnc.sk $_i$  is the secret key that corresponds to WKEnc.pk $_i$

$$(\text{WKEnc.sk}_i, \text{WKEnc.pk}_i) \in \text{SUPP}(\text{KeyGen}(1^\lambda))$$

**Fig. 3.** The relation  $\mathcal{R}_{\text{KEYGEN}}$

$\text{MINT}(x, \text{PK}_i, \text{PK}_i^{\text{pub}}, \text{SK}_i^{\text{pub}}, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}})$  User  $P_i$  does:

1. Set  $\text{tx}_{\text{MINT}} = (x, \text{PK}_i^{\text{pub}}, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}})$
2. Compute  $\sigma = \text{Sign}(\text{sk}_i, \text{tx}_{\text{MINT}})$  and broadcast  $(\text{tx}_{\text{MINT}}, \sigma)$

**Fig. 4.** Transferring funds from public to private account

**Public transfers** (Fig 4) To add funds (say an amount  $x$ ) to their private balance, a party  $P_i$  runs the **MINT** algorithm, which transfers funds from the public account to the private account. A miner  $Q_j$  upon receiving this transaction verifies that the transaction is valid (by running ValidTx) and that the public account  $\text{PK}_i^{\text{pub}}$  indeed has public funds greater than the minted value  $x$  by running the **PROCESSTRANSACTION** algorithm. (See Fig 8). If the transaction is valid,  $Q_j$  computes encryptions of a binary decomposition of  $x$  using FHE.pk $_i$  and homomorphically adds these ciphertexts to  $\mathcal{T}_{\text{privAccounts}}[\text{PK}_i]$ .

**Private Transfers** (Fig 5) User  $P_S$  executes the **TRANSFER** algorithm to privately transfer funds to  $P_R$ .  $P_S$  first receives the latest blockchain  $\mathcal{C}$  and  $\mathcal{T}_{\text{privAccounts}}[\text{PK}_S] = \mathbf{C}_S$  and a path $_S$  (from the root  $\text{rt}_{\mathcal{T}_{\text{privAccounts}}}$  to the leaf  $\mathbf{C}_S$ ) from a full node. We note that there exist works[50,49] that use PIR/ORAM-

like techniques to retrieve account state in a privacy-preserving way.  $P_S$  transfers funds to  $P_R$  as follows:  $P_S$  first encrypts the sender's public key ( $\text{WKEnc.pk}_S$ ) under  $\text{WKEnc.pk}_S$  and receiver's public key ( $\text{WKEnc.pk}_R$ ) (binary decomposed) under  $\text{WKEnc.pk}_R$ .  $P_S$  then encrypts the value to be credited (denoted  $x$ ) under the receiver's public key and the value to be debited under the sender's public key. The value  $x$  is upper-bounded by  $\text{MAX}$  (the maximum possible value that can be transferred) which is  $\mu$  bits long. The user  $P_S$  then proves that the transaction is computed correctly using a zero-knowledge proof, which we describe in more detail below.

$\text{TRANSFER}(\text{PK}_S, \text{SK}_S, \text{PK}_R, x, ep, R, \mathcal{C}_{\text{loc}}, \text{path}_i, \mathbf{C}_i)$  User  $P_i$  does:

1. Let  $\text{rt} = \text{rt}_{\mathcal{T}_{\text{pubAccounts}}} \parallel \text{rt}_{\mathcal{T}_{\text{privAccounts}}}$  be the root at current slot  $sl$  in  $\mathcal{C}_{\text{loc}}$
2. Let locally stored  $\mathbf{C}_i = \mathcal{T}_{\text{privAccounts}}[\text{PK}_S]$  at slot number  $sl$
3. Encrypt sender's identity  
For  $i \in [\lambda]$ , compute  $C_{S,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_i)$ , where  $b_i = \text{WKEnc.pk}_S[i]$ . Let  $\mathbf{C}_S := (C_{S,1}, \dots, C_{S,\lambda})$ .
4. *Encrypt receiver's identity*  
For  $i \in [\lambda]$ , compute  $C_{R,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_R, b_i)$ , where  $b_i = \text{WKEnc.pk}_R[i]$ . Let  $\mathbf{C}_R := (C_{R,1}, \dots, C_{R,\lambda})$
5. *Encrypt debited value*  
For  $i \in [\mu]$ , compute  $C_{D,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_i)$ , where  $b_i = x[i]$ . Let  $\mathbf{C}_D := (C_{D,1}, \dots, C_{D,\mu})$
6. Encrypt credited value  
For  $i \in [\mu]$ , compute  $C_{C,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_R, b_i)$ , where  $b_i = x[i]$ . Let  $\mathbf{C}_C := (C_{C,1}, \dots, C_{C,\mu})$
7. Compute PRF output: Compute  $\text{PRFOut} = \text{PRF}(k, ep)$
8. Compute a zero-knowledge proof for transaction validity:  
Let  $x = \{\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \text{rt}, ep\}$ . Let  $w = \{\text{PK}_S, \text{SK}_S, \text{PK}_R, x, k, \text{C}_{\text{PRF}}, v_S, \mathbf{C}_i, \text{path}\}$ . Send  $(\text{Prove}, \text{sid}, x, w)$  to  $\mathcal{F}_{\text{nizk}}$  to prove that  $(x, w)$  satisfies relation  $\mathcal{R}_{\text{TRANSFER}}$  (Fig 6) and receive  $\pi$ .
9. Return  $\text{tx} = (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$

Fig. 5. Transfer algorithm

As discussed in the introduction (c.f. *Concurrency Issues*), we must ensure that a malicious sender cannot double-spend from their account. We resolve this issue by ensuring that a party can submit only up to one transaction per epoch. We achieve this by including the output of a pseudorandom function PRF with every transaction.

The PRF takes as input the current epoch  $ep$  and therefore if a user attempts to speak twice within the same epoch, a miner would see the same PRF output (since PRFs are deterministic) and rejects the second transaction. We prevent denial-of-service attacks where an adversary front-runs a user's transaction by submitting an adversarial transaction with the same PRFOut as the target by using PRFs that are secure under malicious key generation.

*Zero Knowledge Proofs for Transfer Transactions* Our construction invokes the  $\mathcal{F}_{\text{nizk}}$  functionality for a specific relation (see Fig. 6). A transfer transaction is of the form:  $(\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_C, \mathbf{C}_D, \text{PRFOut}, \pi)$ . In this transaction, the proof  $\pi$  needs to prove that certain conditions are satisfied by the transfer transaction. The conditions are: (a) The sender has a balance greater than the value to be transferred at epoch  $ep$  (b) the value debited is equal to the value credited (c) the sender speaks only once in the current epoch (d) the credited value is positive.

#### The relation

- Statement:  $x = (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_C, \mathbf{C}_D, \text{PRFOut}, \text{rt}_{\mathcal{T}_{\text{privAccounts}}}, ep)$ . The statement specifies the encryptions of the sender and receiver identities  $\mathbf{C}_S, \mathbf{C}_R$ , encryptions of the values to be credited and debited

- $C_D, C_C$ , the output of the PRF (PRFOut), the root of a Merkle tree over private state ( $\mathcal{T}_{\text{privAccounts}}$ ) in the epoch  $ep$  denoted  $rt_{\mathcal{T}_{\text{privAccounts}}}$ .
- Witness:  $w = (PK_S, SK_S, PK_R, x, v_S, C, \text{path}, r_{\text{PRF}})$  where  $PK_S = (k\text{-ct}_S, \text{FHE.pk}_S, \text{WKEnc.pk}_S, vk_S, C_{\text{PRF}})$ . The witness specifies the public keys of the sender and the receiver, the value to be transferred, the balance and the entry in the private state corresponding to  $PK_S$  and an authentication path from the sender's entry in  $\mathcal{T}_{\text{privAccounts}}$  to the root of the Merkle tree on  $\mathcal{T}_{\text{privAccounts}}$ .

Given an instance  $x$ , a witness  $w$  is valid for  $x$  if the relation specified in Figure 6 holds.

Relation  $\mathcal{R}_{\text{TRANSFER}}$ :

$C_S$  is the encryption of the bit-representation of the public key of the sender ( $\text{WKEnc.pk}_S$ ) encrypted under the public key  $\text{WKEnc.pk}_S$ .

$$C_S = \{\text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_j)\} \text{ such that } \sum_{j=0}^{\lambda} b_j \times 2^j = \text{WKEnc.pk}_S$$

$C_R$  is the encryption of the bit-representation of the public key of the receiver ( $\text{WKEnc.pk}_R$ ) encrypted under the public key  $\text{WKEnc.pk}_R$ .

$$C_R = \{\text{WKEnc.Enc}(\text{WKEnc.pk}_R, b_j)\} \text{ such that } \sum_{j=0}^{\lambda} b_j \times 2^j = \text{WKEnc.pk}_R$$

$C_C$  is the encryption of the bit-representation of the value  $x$  to be credited to the receiver's account, encrypted under the public key of the receiver  $\text{WKEnc.pk}_R$ .

$$C_C = \{\text{WKEnc.Enc}(\text{WKEnc.pk}_R, b_j)\} \text{ such that } \sum_{j=0}^{\mu} b_j \times 2^j = x$$

$C_D$  is the encryption of the bit-representation of the value  $x$  to be debited from the sender's account, encrypted under the public key of the sender  $\text{WKEnc.pk}_S$ .

$$C_D = \{\text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_j)\} \text{ such that } \sum_{j=0}^{\mu} b_j \times 2^j = x$$

The value  $x$  is not negative and is less than the max possible value MAX.  $x \in [0, \text{MAX}]$   
 The sender knows the secret key associated with the account from which the funds are to be debited.

$$(\text{ValidPath}((PK_S, C), \text{path}, rt_{\mathcal{T}_{\text{privAccounts}}}) = 1) \wedge$$

$$(PK_S = (\text{FHE.pk}_S, \text{WKEnc.pk}_S, k\text{-ct}_S, C_{\text{PRF}}))$$

The balance associated with the sender's account is greater than the value  $x$

$$\text{FHE.Dec}(\text{FHE.sk}_S, C) = v \wedge v - x \in [0, \text{MAX}]$$

The PRF output was computed correctly

$$\text{PRFOut} = \text{PRF}(k, ep) \wedge C_{\text{PRF}}^S = \text{Com}(k; r_{\text{PRF}})$$

**Fig. 6.** The relation  $\mathcal{R}_{\text{TRANSFER}}$

**Updating the state.** A miner  $Q_j$  upon receiving a transaction ( $\text{tx}_{\text{MINT}}$  or  $\text{tx}_{\text{TRANSFER}}$ ) updates the state by running the PROCESSTRANSACTION algorithm. As the identities and the values are

encrypted using a key-private encryption scheme,  $Q_j$  does not know which entries to update in table  $\mathcal{T}_{\text{privAccounts}}$ . Therefore the  $Q_j$  must update all the entries in  $\mathcal{T}_{\text{privAccounts}}$ . To this end, the miner updates the ciphertexts in each entry of  $\mathcal{T}_{\text{privAccounts}}$  as in Figure 7. We present the proof of correctness of this update in Appendix A and also present a simple example in Fig 14 and Fig 15 that may aid the reader in understanding the UpdateCiphertext function.

### 4.3 Practical Considerations

**Paying gas fees.** In the presentation of our protocol, we don't specify how parties can pay gas fees to the miner as part of the transaction. We can add a public component to the transaction as follows: The sender adds the gas value in the clear, and encrypts  $gas + x$  as the debited value. The zk proof now proves that sum of the  $x$  and the public gas fee is equal to the debited value.

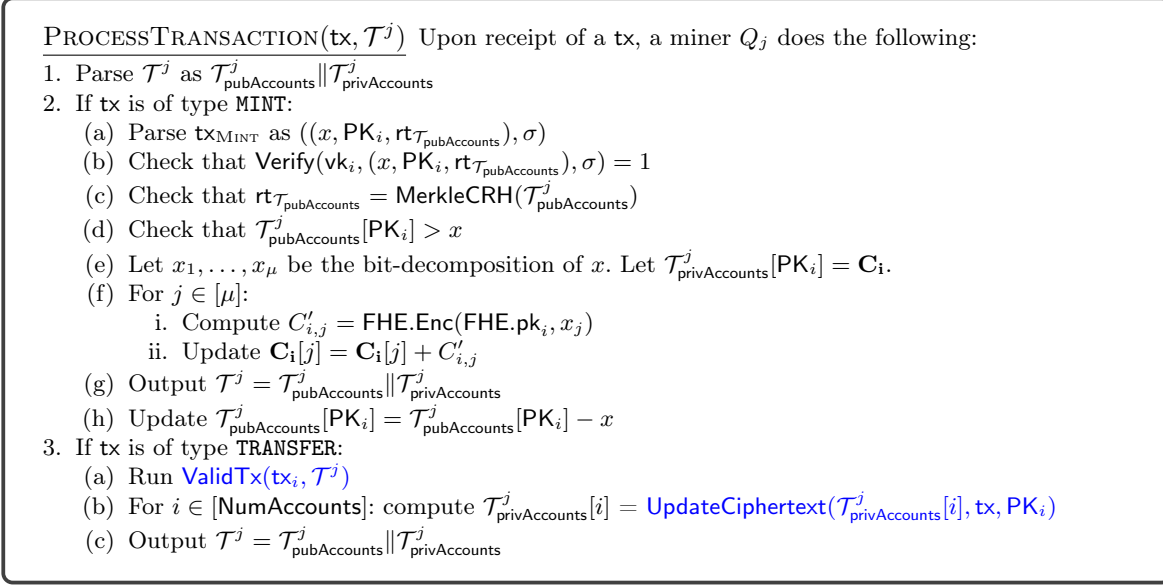

**UpdateCiphertext( $C_i, tx, PK_i$ )**

1. Parse  $tx$  as  $(C_S, C_R, C_D, C_C, PRFOut, \pi)$
2. Parse  $PK_i$  as  $(k-ct_i, FHE.pk_i, WKEnc.pk_i, vk_i, C_{PRF})$
3. *Obliviously decrypt identity ( $C_S$ ) ciphertext with  $k-ct_i$  (encryption of  $WKEnc.sk_i$ ) to get an encryption of some  $pk^*$  under  $FHE.pk_i$* 
  - For  $j \in [\lambda]$ , compute  $C_{i,j}^{id} = FHE.Eval(FHE.pk_i, WKEnc.Dec, (k-ct_i, C_S[j]))$
  - Compute  $C_i^{id} = (C_{i,1}^{id}, \dots, C_{i,\lambda}^{id})$
  - // if  $i$  corresponds to  $P_S$ , then  $C_i^{id}$  is an encryption of the receiver's public key, i.e.  $pk^* = WKEnc.pk_S$
4. *Obliviously compute  $pk^* \oplus \overline{WKEnc.pk_S}$  bitwise (where  $\overline{WKEnc.pk_S}$  is the negated bitwise decomposition of  $WKEnc.pk_S$ ) as follows:*
  - For  $j \in [\lambda]$ , compute  $C_{i,j}^{preflag} = FHE.Eval(FHE.pk_i, \oplus, (\overline{WKEnc.pk_S}[j], C_{i,j}^{id}))$
  - Compute  $C_i^{preflag} = (C_{i,1}^{preflag}, \dots, C_{i,\lambda}^{preflag})$
  - // if  $i$  corresponds to  $P_S$ ,  $C_i^{preflag}$  is an encryption of all ones
5. *Obliviously multiply the bits of preflag to get a flag bit*
  - Compute  $C_i^{flag} = FHE.Eval(FHE.pk_i, \times, (C_{i,1}^{preflag}, \dots, C_{i,\lambda}^{preflag}))$
  - // if  $i$  corresponds to  $P_S$ ,  $C_i^{flag}$  is an encryption of 1, else encryption of 0
6. *Obliviously decrypt value to be debited ( $C_D$ ) with  $k-ct_i$  to get an encryption of some  $x^*$  under  $FHE.pk_i$* 
  - For  $j \in [\mu]$ , compute  $C_{i,j}^x = FHE.Eval(FHE.pk_i, WKEnc.Dec, (k-ct_i, C_D[j]))$
  - Set  $C_i^x = (C_{i,1}^x, \dots, C_{i,\mu}^x)$
  - // if  $i$  corresponds to  $P_S$ ,  $C_i^x$  is an encryption of the value  $x$ , i.e.  $x^* = x$ , else  $x^*$  is random
7. *Obliviously multiply the flag bit with  $x^*$* 
  - For  $j \in [\mu]$ , compute  $C_{i,j}^{upd} = FHE.Eval(FHE.pk_i, \times, (C_{i,j}^x, C_{i,j}^{flag}))$
  - Set  $C_i^{upd} = (C_{i,1}^{upd}, \dots, C_{i,\mu}^{upd})$
  - // if  $i$  corresponds to  $P_S$ ,  $C_i^{upd}$  is an encryption of the value  $x$ , else 0
8. *Obliviously subtract  $x^*$  from the balance of  $P_i$* 
  - For  $j \in [\mu]$ , compute  $FHE.Eval(FHE.pk_i, FullSubtractor^a, (C_{i,j}, C_{i,j}^{upd}))$
  - Set  $C_i = (C_{i,1}, \dots, C_{i,\mu})$
  - // if  $i$  corresponds to  $P_S$ , the balance of  $P_i$  is subtracted by  $x$ , else the balance of  $P_i$  stays the same (0 is subtracted from the balance)

Do the same computations as above with  $(C_R, C_C)$  instead of  $(C_S, C_D)$ , except that in Step 8, obliviously add  $(x^* \times flag)$  to the balance of  $P_i$ , i.e. compute  $FHE.Eval(FHE.pk_i, FullAdder, (C_{i,j}, C_{i,j}^{upd}))$

<sup>a</sup> for completeness, we present the logic for full adder and full subtracter in Appendix F

**Fig. 7.** Updating the private state entry  $\mathcal{T}_{privAccounts}[PK_i]$  with a transaction  $tx$

**Fig. 8.** Verification of transactions and updating the state

**Transaction size and processing time.** We present an estimate on the size of our transactions and the time taken to process a transaction. A transfer transaction is of the form  $\mathbf{tx} = (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$ . The ciphertexts  $\mathbf{C}_S$  and  $\mathbf{C}_R$  encrypt vectors of size  $\lambda = 128$  and  $\mathbf{C}_D, \mathbf{C}_C$  encrypt vectors of size  $\mu = 20$ . PVW [41] ciphertexts ( $\in (\mathbb{Z}_q^\lambda, \mathbb{Z}_q^\mu)$ ) present an encryption scheme where we can efficiently pack these ciphertexts into one ciphertext. Therefore  $\mathbf{C}_S + \mathbf{C}_D : (\lambda + \mu) \times \lambda + (\lambda \times \lambda)$  bits =  $(128 + 20) \times 128 + 128 \times 128 = 8832$  bytes and  $\mathbf{C}_S + \mathbf{C}_D = 8832$  bytes. Assuming Groth16[26] proofs and SHA for the PRF, the transaction size is approximately 18KB.

## 5 UC-secure privacy-preserving payments

In the previous section we presented algorithms for PriFHEte payment system. To show that our algorithms can be used to instantiate a privacy-preserving account-based cryptocurrency, we present a UC protocol that makes use of the algorithms to realize the  $\mathcal{G}_{\text{PL}}$  ideal functionality. In this section we first describe the  $\mathcal{G}_{\text{PL}}$  ideal functionality, and then describe how the PriFHEte algorithms will be used to construct a protocol that will realize the  $\mathcal{G}_{\text{PL}}$  functionality.

### 5.1 The $\mathcal{G}_{\text{PL}}$ functionality [30]

The  $\mathcal{G}_{\text{PL}}$  functionality (Figure 16 and 17) captures an ideal private ledger functionality. We describe the different interfaces of the functionality by separately considering the transaction layer and the consensus layer. Before we explain the interface, we describe the variables associated with the functionality: the **state** is the state of the ledger that includes blocks of transactions and the **buffer** is a list of unconfirmed transactions that have not yet been added to the **state**.

In the transaction layer, a party should be able to submit a transaction. The  $\mathcal{G}_{\text{PL}}$  functionality therefore includes a **SUBMIT** command in its interface that allows parties to submit their transactions. The  $\mathcal{G}_{\text{PL}}$  functionality on receiving the **SUBMIT** command, creates a transaction ID, checks if the transaction is valid using the **ValidTx** predicate. We note that **ValidTx** is specific to the protocol that realizes the functionality. In our setting this predicate is instantiated as in Figure 18. The predicate

returns true only if the value of the transaction is less than the balance of the sending account and that there is no other transaction from this sender in the current epoch. The adversary is informed that a transaction was received and a *blinded* version of the transaction is sent to the adversary. Parties should also be able to join the system at any point in time. Parties join the system by simply registering with the  $\mathcal{G}_{\text{PL}}$  functionality.

In the consensus layer, the functionality guarantees that the parties agree on a common **state**. But this is not possible in the real-world due to network delays or an adversarial influence. Therefore, the functionality guarantees that there is a prefix of the **state** that is common to all parties. Since different parties may have different local chains, a pointer  $\text{pt}_i$  denotes length of the local chain of  $P_i$ . To read the **state** of the ledger, the party issues a **READ** command and is returned a blinded version of the **state** upto either block number  $\text{pt}_i$  or  $|\text{state}|$  (whichever is smaller). The adversary is given the power to determine the view of all parties as long as they have a common prefix. The adversary uses the **SET-SLACK** and **DESYNC-STATE** interfaces to achieve this.

In this description, we have not yet discussed how the ideal functionality extends the **state** with new blocks of transactions. In the real-world a party may be selected to propose the next block on the chain depending on some lottery protocol that is defined with respect to the consensus protocol. Similarly, in the ideal world a party sends the **MAINTAIN-LEDGER** command to the  $\mathcal{G}_{\text{PL}}$  functionality. The functionality records this command, and informs the ideal-world adversary of this command. A new block is then proposed by the ideal-world adversary using the **NEXT-BLOCK** command. This new block is a list of transactions along with a flag called **hFlag** that indicates if the block is proposed on behalf of an honest party or malicious party. The ideal functionality records this block. When the ideal functionality is queried with any command, the functionality updates the **state** with these blocks. Note that an adversary can of course propose *bad* blocks that have illegal transactions or transactions that are inconsistent with the **state**. The  $\mathcal{G}_{\text{PL}}$  functionality therefore evaluates an **ExtendPolicy** function on the block. This function checks if the block is valid and if not, proposes a default block that is used to extend the **state** of the system.

## 5.2 Protocol $\Pi_{\text{PriFHEte}}$

Now that we have explained the  $\mathcal{G}_{\text{PL}}$  functionality, we are ready to present our main protocol. More specifically, we will present how we integrate the **PriFHEte** algorithms from Section 4 in the main protocol. We will then prove that this protocol realizes the  $\mathcal{G}_{\text{PL}}$  ideal functionality.

Recall, from Section 4 that the **MINT** and **TRANSFER** invoked the  $\mathcal{F}_{\text{nizk}}$  ideal functionality. Apart from the  $\mathcal{F}_{\text{nizk}}$  functionality, our main protocol will make calls to other functionalities. We give an overview of these functionalities below:

1.  $\mathcal{G}_{\text{clock}}$ : In both the real world and the ideal world, our protocols require a notion of time. This is achieved using the  $\mathcal{G}_{\text{clock}}$  functionality (see Figure 24). The clock maintains a variable  $\tau$  that denotes the current time. When all registered honest parties (at a given time  $\tau$ ) signal the functionality that they are done with the current round, the functionality advances the time counter  $\tau$ . Parties can also query the functionality to read the current time.
2.  $\mathcal{F}_{\text{N-MC}}$ : Parties in the real-world multicast transactions and blocks to their peers.  $\mathcal{F}_{\text{N-MC}}$  models a network functionality (see App. A2 of [7]) that captures a multicast network. We stress that this network functionality does not give any anonymity properties.
3.  $\mathcal{F}_{\text{anon-selection}}$ : As described above, parties run a lottery to check if they are elected to propose blocks and if elected they broadcast the block with an anonymous proof. The anonymous selection functionality (Figure 26 and defined in [9]) allows parties to check if they are eligible to win a lottery. The functionality also provides an interface for parties to receive a proof of winning the lottery, and an interface to verify the proofs.
4.  $\mathcal{F}_{\text{nizk}}$ : As discussed in Section 4 parties are required to attach a zero-knowledge proof that proves that the submitted transactions are well-formed. The parties therefore query a non-interactive zero knowledge functionality (Figure 25 and defined in [30]). This functionality allows generating proofs that a statement  $x$  is in a given NP language  $\mathcal{L}$ , with a witness  $w$ .

**Registration/Deregistration:** Upon receiving (REGISTER,  $\mathcal{R}$ ) where  $\mathcal{R} \in \{\mathcal{G}_{\text{clock}}, \mathcal{G}_{\text{PL}}\}$  from the environment  $\mathcal{Z}$ , a party  $P_i$  does:

- if  $\mathcal{R} = \mathcal{G}_{\text{clock}}$ , register with the  $\mathcal{G}_{\text{clock}}$  functionality.
- if  $\mathcal{R} = \mathcal{G}_{\text{PL}}$  and  $P_i$  has not registered with  $\mathcal{G}_{\text{clock}}$  ignore the command, else register with the  $\mathcal{F}_{\text{N-MC}}, \mathcal{F}_{\text{nizk}}, \mathcal{F}_{\text{anon-selection}}$  functionalities

(The full specification is presented in Ouroboros Genesis [6])  
 $P_i$  then calls **Initialization-PrivProtocol** returning  $(\text{PK}_i, \text{SK}_i, \pi_{\text{KeyGen}})$ .  
 // Transaction layer

**Submitting a transaction:** Upon receiving  $I = (\text{SUBMIT}, \text{sid}, \text{tx})$  from  $\mathcal{Z}$ ,

- $P_i$  calls **SubmitXfer**( $\text{tx}, \mathcal{C}_{\text{loc}}^i$ ), where  $\mathcal{C}_{\text{loc}}^i$  is local chain maintained by  $P_i$ .

// Consensus layer

**Maintaining the ledger:** Upon receiving  $I = (\text{MAINTAIN-LEDGER}, \text{sid})$  from  $\mathcal{Z}$ ,

- the party  $P_i$  invokes **LedgerMaintenance**( $\mathcal{C}_{\text{loc}}^i, P_i$ )

**Reading the state:** Upon receiving  $I = (\text{READ})$  from  $\mathcal{Z}$ ,

- the party  $P_i$  invoke the protocol **ReadState**( $\text{sid}, \mathcal{C}_{\text{loc}}^i, P_i$ ).

*Handling external (protocol-unrelated calls) to the clock:* as in Ouroboros Genesis [6].

**Fig. 9.** The protocol  $\Pi_{\text{PriFHEte}}$

In Figure 9 we present the overall protocol that realizes the  $\mathcal{G}_{\text{PL}}$  ideal functionality. In our protocol, a block is proposed in a slot. Every  $\eta$  slots constitute an epoch  $ep$ . We now present an overview of the protocol.

Protocol Initialization-PrivProtocol( $P_i, \text{sid}$ )  $\rightarrow$   $(\text{PK}_i, \text{SK}_i, \pi_{\text{KeyGen}})$ :  
 These steps are executed in a (MAINTAIN-LEDGER, sid)-interruptible manner:

1. Compute  $(\text{PK}_i, \text{SK}_i, \pi_{\text{KeyGen}}) \leftarrow \text{KEYGENERATION}(\lambda)$
2. Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
3. If  $\tau = 0$  then execute the following steps in a (MAINTAIN-LEDGER, sid)-interruptible manner:
  - (a) Send (claim, sid,  $P_i, \text{PK}_i$ ) to  $\mathcal{F}_{\text{init}}$ .
  - (b) Send (CLOCK-UPDATE,  $\text{sid}_C$ ) to  $\mathcal{G}_{\text{clock}}$
  - (c) Use clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$ ; give up the activation.
4. Else
  - (a) Send (gen-block, sid,  $P_i$ ) to  $\mathcal{F}_{\text{init}}$ . If  $\mathcal{F}_{\text{init}}$  signals an error then halt. Otherwise, receive from  $\mathcal{F}_{\text{init}}$  the response (gen-block, sid,  $\mathbb{G} = (\mathbb{C}_1, \eta_1)$ )
  - (b) Set  $\mathcal{C}_{\text{loc}} \leftarrow (\mathbb{G})$
  - (c) Send (NEW-PARTY, sid,  $P_i, \text{PK}_i, \pi_{\text{KeyGen}}$ ) to  $\mathcal{F}_{\text{N-MC}}$
5. Return  $(\text{PK}_i, \text{SK}_i, \pi_{\text{KeyGen}})$

**Fig. 10.** Protocol Initialization-PrivProtocol

**Joining the system** Upon receiving a ledger-registration request from the environment, the party registers with each of the functionalities. Once registered with the functionalities, the party

is considered online. The party then becomes operational by invoking the Initialization-PrivProtocol protocol. Upon execution of the Initialization-PrivProtocol protocol, the party  $P_i$  first generates keys by running the **KEYGENERATION**( $\lambda$ ) algorithm (as presented in Section 4). The Initialization-PrivProtocol protocol works in two modes depending on the whether or not the current round is the genesis round. In the genesis mode, which is executed when  $\tau = 0$ , the party interacts with  $\mathcal{F}_{\text{init}}$  to register its keys. The  $\mathcal{F}_{\text{init}}$  functionality calls the **REGISTRATION** function here to add the party's entry to  $\mathcal{T}_{\text{privAccounts}}$ . In the non-genesis mode, as in [6], the protocol Initialization-PrivProtocol queries  $\mathcal{F}_{\text{init}}$  to receive the genesis block. If the underlying protocol is a Proof-of-Stake protocol, the parties need to claim stake in the genesis mode, and in the non-genesis mode the  $\mathcal{F}_{\text{init}}$  functionality determines the lottery difficulty for the newly joined  $P_i$ . We refer to [6] for details. Finally, the party announces to the network that it is a new party by broadcasting (**NEW-PARTY**,  $\text{sid}, P_i, \text{PK}_i$ ). This interaction is presented in more details in Figure 10.

Protocol SubmitXfer( $\text{tx}, \mathcal{C}_{\text{loc}}$ )

1. Execute **FetchInformation** (as in Ouroboros Genesis (full version) [7]) to receive the newest messages of the round; denote the output by  $(\mathcal{C}_1, \dots, \mathcal{C}_M), (\text{tx}_1, \dots, \text{tx}_k)$ .
2. Set  $\mathcal{N} \leftarrow \{\mathcal{C}_1, \dots, \mathcal{C}_M\}$
3. Invoke protocol **SelectChain**( $\mathcal{N}, \mathcal{C}_{\text{loc}}, \dots$ ) (as defined in Ouroboros Genesis [6]) and receive an updated chain  $\mathcal{C}_{\text{loc}}$ .
4. If  $\text{tx} = (\text{TRANSFER}, \text{tx}')$ :
  - (a) Let  $(\text{PK}_S, \text{PK}_R, x) \leftarrow \text{tx}'$
  - (b) Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
  - (c) Let  $\text{tx}^* := \text{TRANSFER}(\text{PK}_S, \text{PK}_R, x, ep, R, \mathcal{C}_{\text{loc}}, \mathbf{C}_i)$
  - (d) Submit (**MULTICAST**,  $\text{tx}^*$ ) to  $\mathcal{F}_{\text{N-MC}}$
5. Else if  $\text{tx} = (\text{MINT}, \text{tx}')$ 
  - (a) Let  $(\text{PK}_S, x) \leftarrow \text{tx}'$
  - (b) Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
  - (c) Let  $\text{tx}^* := \text{MINT}(x, \text{PK}_S, \text{SK}_S, \text{rt}_{\text{pubAccounts}})$
  - (d) Submit (**MULTICAST**,  $\text{tx}^*$ ) to  $\mathcal{F}_{\text{N-MC}}$

**Fig. 11.** Protocol SubmitXfer

**Submitting a transaction.** A party  $P_S$  receives a **SUBMIT** command from the environment. Recall that the transaction could be either a **TRANSFER** transaction or a **MINT** transaction. If the transaction is of type **TRANSFER**, then parse the command as **TRANSFER**||( $\text{PK}_S, \text{PK}_R, v$ ) where  $\text{PK}_S$  is the public key associated with the account of the sender and  $\text{PK}_R$  is the public key associated with the account of the receiver and  $x$  is the value to be transferred.

The transaction is computed using the **TRANSFER** algorithm defined in Figure 5. The transaction is then broadcast to the network by submitting (**MULTICAST**,  $\text{tx}$ ) to the network functionality ( $\mathcal{F}_{\text{N-MC}}$ ). Similarly, if the command is of type **MINT**, then parse the command as **MINT**||( $\text{PK}_S, v$ ). The real-world transaction is computed using **MINT** algorithm defined in Figure 4 and is broadcast using the  $\mathcal{F}_{\text{N-MC}}$  functionality.

**Protocol LedgerMaintenance**( $\mathcal{C}_{loc}, Q_j$ )

The following steps are executed in a (MAINTAIN-LEDGER, sid)-interruptible manner:

1. Execute **FetchInformation** (as in Ouroboros Genesis [7]) to receive the newest messages of the round; denote the output by  $(\mathcal{C}_1, \dots, \mathcal{C}_M), (\mathbf{tx}_1, \dots, \mathbf{tx}_k)$ .
2. Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
3. Set  $\text{buffer} \leftarrow \text{buffer} \parallel (\mathbf{tx}_1, \dots, \mathbf{tx}_k), t_{on} \leftarrow \tau, \mathcal{N} \leftarrow \{\mathcal{C}_1, \dots, \mathcal{C}_M\}$
4. Invoke protocol **SelectChain**(...) (as defined in Ouroboros Genesis [6]) and receive an updated  $\mathcal{C}_{loc}^j$ . Let  $\mathcal{C}_{loc}^*$  be the original local chain.
5. Let  $\mathcal{U}$  be the set of transactions that are in  $\mathcal{C}_{loc}^j$  but not in  $\mathcal{C}_{loc}^*$ .
6. Invoke protocol **LotteryProcedure**( $Q_j, ep, sl, \text{buffer}, \mathcal{C}_{loc}^j, \mathcal{U}$ ) (in a (MAINTAIN-LEDGER, sid)-interruptible manner)
7. Send (CLOCK-UPDATE,  $\text{sid}_C$ ) to  $\mathcal{G}_{\text{clock}}$ .

**Fig. 12.** Protocol LedgerMaintenance

**Maintaining the ledger.** Upon receiving a MAINTAIN-LEDGER command from the environment, a miner  $Q_j$  invokes the LedgerMaintenance algorithm. The algorithm invokes the **FetchInformation** command as defined in [7]. This algorithm fetches the recent messages in the round - this includes both the local chains broadcast by other parties  $\mathcal{C}_1, \dots, \mathcal{C}_M$  and the transactions broadcast by other parties  $\mathbf{tx}_1, \dots, \mathbf{tx}_k$ . The miner then updates the buffer with these transactions and then selects the longest valid chain using the SelectChain algorithm defined in [6] to update its local chain  $\mathcal{C}_{loc}^j$ .  $Q_j$  then invokes the LotteryProcedure algorithm to check if it is selected as a leader to propose the next block on the chain.

The LotteryProcedure (see Figure 13) first sends the ELIGIBILITY-CHECK command to the  $\mathcal{F}_{\text{anon-selection}}$  functionality to check if the miner  $Q_j$  is eligible to propose the next block on the chain. If eligible, the miner first computes a local state based on the recently updated local chain  $\mathcal{C}_{loc}^j$ . Now to create the next block on the chain, the miner iterates through the buffer and checks if each transaction is valid (using the ValidTx predicate, defined in Figure 22). If the transaction is valid, the miner updates the state with this transaction by running **PROCESSTRANSACTION**( $\mathbf{tx}_i, \mathcal{T}^j$ ). The miner then adds this transaction to a block. The miner also adds the root of a Merkle tree computed over the updated state  $\mathcal{T}^j$  and broadcasts the block using the  $\mathcal{F}_{\text{N-MC}}$  functionality.

To join the system, a new party must first register with the hybrid functionalities -  $\mathcal{G}_{\text{clock}}, \mathcal{F}_{\text{init}}, \mathcal{F}_{\text{nizk}}, \mathcal{F}_{\text{N-MC}}$  and  $\mathcal{F}_{\text{anon-selection}}$ . The party then runs the Initialization-PrivProtocol protocol, which internally runs the algorithm **KEYGENERATION** to return  $(\text{PK}_i, \text{SK}_i, \pi_{\text{KeyGen}})$ . The party then broadcasts to the network the message (NEW-PARTY,  $\text{sid}, P_i, \text{PK}_i, \pi_{\text{KeyGen}}$ ). A miner upon receiving this message and tasked with maintaining the ledger updates the state by running the **REGISTRATION** algorithm.

Protocol LotteryProcedure( $k, Q_j, ep, sl, \text{buffer}, \mathcal{C}_{\text{loc}}^j, \mathcal{U}$ ) The following steps are executed in a (MAINTAIN-LEDGER, sid)-interruptible manner:

1. Let  $\mathcal{T}^j = (\mathcal{T}_{\text{pubAccounts}}^j \parallel \mathcal{T}_{\text{privAccounts}}^j)$  be the state associated with  $\mathcal{C}_{\text{loc}}^j$  maintained by  $Q_j$
2. Send (ELIGIBILITY-CHECK, sid, ( $sl, ep$ )) to  $\mathcal{F}_{\text{anon-selection}}$  and receive (ELIGIBILITY-CHECK,  $b$ ). If  $b = 0$ , exit the protocol.
3. Else update  $\mathcal{T}^j \leftarrow \text{PROCESSTRANSACTION}(\text{tx}, \mathcal{T}^j)$  for each  $\text{tx} \in \mathcal{U}$ , initialize  $\mathbf{N} = \emptyset$  and for each  $\text{tx}_i \in \text{buffer}$  do (or until  $\mathbf{N}$  can not increase any more):
  - (a) if  $\text{ValidTx}(\text{tx}_i, \mathcal{T}, \mathcal{C}_{\text{loc}}^j)$  then  $\mathbf{N} \leftarrow \mathbf{N} \parallel \text{tx}_i$
  - (b) Remove  $\text{tx}_i$  from buffer
  - (c) If  $\text{tx}_i = (\text{NEW-PARTY}, \text{PK}_i)$ , then run  $\text{REGISTRATION}(\text{PK}_i, \mathcal{T}^j)$
  - (d) Set  $B' \leftarrow \text{blockify}(\mathbf{N})$  and update  $\mathcal{T}^j \leftarrow \text{PROCESSTRANSACTION}(\text{tx}_i, \mathcal{T}^j)$
4. Set  $\text{ptr} \leftarrow H(\mathcal{C}_{\text{loc}})$
5. Compute  $\text{rt}_{\text{privAccounts}} = \text{MerkleCRH}(\mathcal{T}_{\text{privAccounts}})$  and  $\text{rt}_{\text{pubAccounts}} = \text{MerkleCRH}(\mathcal{T}_{\text{pubAccounts}})$  and set  $\text{rt} = (\text{rt}_{\text{privAccounts}} \parallel \text{rt}_{\text{pubAccounts}})$ .
6. Send (CREATE-PROOF, sid, ( $ep, sl$ ),  $\mathcal{T}$ ) to  $\mathcal{F}_{\text{anon-selection}}$  and receive  $\pi$ . Set  $\text{tx}_{\text{lead}} = ((ep, sl), \text{ptr}, \text{rt}, \pi)$
7. Set  $B \leftarrow (\text{tx}_{\text{lead}}, B')$  and  $\mathcal{C}_{\text{loc}} = \mathcal{C}_{\text{loc}} \parallel B$
8. Send (MULTICAST, (sid,  $\text{tx}_{\text{lead}}$ )) to  $\mathcal{F}_{\text{N-MC}}^{\text{tx}}$  and (MULTICAST, sid,  $\mathcal{C}_{\text{loc}}$ ) to  $\mathcal{F}_{\text{N-MC}}^{\text{bc}}$  and proceed from here upon next activation of this procedure.
9. While a (LOCK-UPDATE, sid<sub>C</sub>) has not been received during the current round: give up activation, and upon next activation of this procedure, proceed from here.

**Fig. 13.** Proposing a new block if miner wins the lottery

## 6 Security Analysis

In this section we informally argue security of our scheme. We present the full security proofs in Appendix D.

**Theorem 1.** *The protocol  $\Pi_{\text{PrIFHE}_{\text{te}}}$  UC realizes the  $\mathcal{G}_{\text{PL}}$  functionality in the  $(\mathcal{G}_{\text{clock}}, \mathcal{F}_{\text{anon-selection}}, \mathcal{F}_{\text{init}}, \mathcal{F}_{\text{nizk}}, \mathcal{F}_{\text{N-MC}})$ -hybrid world, assuming key-private CPA secure encryption, CPA secure fully homomorphic encryption, secure pseudorandom functions, secure commitment schemes and unforgeable signature scheme.*

*Proof. (Sketch)* To prove UC-security, we must show that there exists a PPT simulator interacting with  $\mathcal{G}_{\text{PL}}$  that generates a transcript that is indistinguishable from the transcript generated by the real world protocol. We first give a high-level overview of the simulator (described in Fig 27, Fig 28 and Fig 29). Our simulator internally simulates the ideal functionalities  $\mathcal{F}_{\text{init}}, \mathcal{F}_{\text{anon-selection}}, \mathcal{F}_{\text{nizk}}, \mathcal{F}_{\text{N-MC}}$  towards the adversary and relays any communication between the adversary and the emulated functionality. Since the general framework of the protocol and functionalities are the same as in Ouroboros Cryptsinous [30] and Genesis [6], we only focus on the simulation that concerns algorithms that we modify or add to. Upon receiving claim command from a party, on behalf of the simulated  $\mathcal{F}_{\text{init}}$  functionality, the simulator first sends a REGISTER command on behalf of the party to the  $\mathcal{G}_{\text{PL}}$  functionality. Upon receiving Prove requests on behalf of the simulated  $\mathcal{F}_{\text{nizk}}$  functionality, the simulator records any witnesses provided by the adversary. Finally, to simulate  $\mathcal{F}_{\text{anon-selection}}$  the simulator executes the commands as the ideal functionality would. The simulation of  $\mathcal{F}_{\text{N-MC}}$  is indeed more interesting than the other functionalities since the simulator needs to create ideal-world transactions and blocks on behalf of the adversary using these transactions. The main idea to retrieve the private information associated with a transaction is to extract the witness that was recorded by the  $\mathcal{F}_{\text{nizk}}$  functionality for the corresponding transaction. Specifically, the simulator retrieves the witness  $w$  from the recorded witnesses in  $\Pi$  and extracts  $\text{PK}_S, \text{PK}_R, v$  and submits an ideal world transaction to  $\mathcal{G}_{\text{PL}}$ . Note that if such a witness does not exist, then the simulator aborts with ZKSoundnessFailure. Since we use

the  $\mathcal{F}_{\text{nizk}}$  functionality, this event occurs with negligible probability. Moreover, if the transaction is of type MINT and the submitted transaction corresponds to that of an honest party, then the simulator aborts with `sigFailure`. Since we use unforgeable signatures the probability of this event occurring is negligible. The adversary may also send new blocks over the  $\mathcal{F}_{\text{N-MC}}$  functionality, the simulator first simulates the transactions in these blocks as described above in the case that ideal transactions for these transactions do not exist. Then the simulator runs `EXTENDLEDGERSTATE` function as defined in Ouroboros Genesis[6], which essentially creates new blocks and submits them to the  $\mathcal{G}_{\text{PL}}$  functionality. To simulate honest transactions, the simulator does the following: upon receiving a registration command, the simulator generates FHE, `WKEnc` and PRF keys as an honest party would. But instead of encrypting the `WKEnc.sk` the simulator encrypts all 0s. By the CPA security of the underlying FHE scheme, this is indistinguishable from the real world to an adversary. Similarly, the commitment to PRF key is replaced by a commitment to 0. Here we leverage the hiding property of the commitment scheme to argue that the two worlds are indistinguishable. To simulate honest transactions, the simulator generates a new `PK, SK` and computes a transfer transaction that sends from `PK` to `PK` a value of 0. By the key-privacy and CPA security of the underlying `WKEnc` scheme, the ideal and the real worlds are indistinguishable to a PPT adversary. The output of the PRF is replaced with a random string, and we leverage the pseudorandomness property of the PRF to argue indistinguishability. We argue in Appendix D through a sequence of hybrids that the real world and the ideal world are indistinguishable.

### A Example to outline state update

**Fig. 14.** Case 1: When the receiver of the payment corresponds to the entry updated in the state. Let the receiver’s public key  $pk_R = 101$ , the value of the transaction be  $x = 001$  and the balance of the receiver be  $v = 001$ . (1) The first step is to decrypt  $Enc(101)$  with  $k-ct_i$ , and since  $i = R$ ,  $C_{id} = FHE.Enc(101)$ . (2) Next,  $C_{id}$  is homomorphically XORed with the complement of  $pk_i$ , which is 010, and this gives an encryption of 111. (3) These ciphertexts are then multiplied together to give a single encryption of 1, this encryption is called  $C_{flag}$ . (4) Next we homomorphically decrypt the value  $C_C$  with  $k-ct_i$  to get an encryption of  $x$  under the FHE key, denoted  $C_v$ . (5) Each of these ciphertexts are then multiplied with the  $C_{flag}$  ciphertext. Since the flag is 1, the value encrypted  $C_v$  does not change. (6) Finally these ciphertexts are added to the encryption of the balance in the state

**Fig. 15.** Case 2: When the receiver of the payment does not correspond to the entry (001) updated in the state. Let the receiver’s public key  $pk_R = 101$ , the value of the transaction be  $x = 001$  and the balance of the receiver be  $v = 001$ . (1) The first step is to decrypt  $\text{Enc}(101)$  with  $k\text{-ct}_i$ , and since  $i \neq R$ ,  $C_{id}$  encrypts a random bit string  $\text{FHE.Enc}(111)$ . (2) Next,  $C_{id}$  is homomorphically XORed with the complement of  $pk_i$ , which is 001, and this gives an encryption of 001. (3) These ciphertexts are then multiplied together to give a single encryption of 0 (4) Next we homomorphically decrypt the value  $C_C$  with  $k\text{-ct}_i$  to get an encryption of  $x$  under the FHE key, denoted  $C_v$ , which is  $\text{FHE.Enc}(011)$  in our example. (5) Each of these ciphertexts are then multiplied with the  $C_{flag}$  ciphertext. Since the flag is 0, the value encrypted  $C_v$  now encrypts 0. (6) Finally these ciphertexts are added to the encryption of the balance in the state which does not change the value encrypted.

*Proof of correctness* To prove the correctness of `PROCESS TRANSACTION` we need to show that the state of the blockchain is updated correctly, i.e. when the entry in  $\mathcal{T}_{\text{privAccounts}}$  does not correspond to that of  $P_S$  (or  $P_R$  w.l.o.g.) the balance remains the same and when the entry does correspond to that of  $P_S$ , the balance is updated with the value in the transaction.

**Case 1:** `UpdateCiphertext`( $\mathcal{T}_{\text{privAccounts}}[\text{PK}_i]$ , ( $C_S, C_R, C_D, C_C, \text{PRFOut}, \pi$ ),  $\text{PK}_i$ ) is executed when  $C_S$  does not correspond to an encryption of  $\text{WKEnc.pk}_i$ . Let  $C_S = \text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_j)$  where  $b_j = \text{WKEnc.pk}_S[j]$  for  $j \in [\lambda]$ .

`UpdateCiphertext` works as follows:

1. Compute  $C_i^{id} = (C_{i,1}^{id}, \dots, C_{i,\lambda}^{id})$ , where  $C_{i,j}^{id} = \text{FHE.Eval}(\text{FHE.pk}_i, \text{WKEnc.Dec}(k\text{-ct}_i, C_S[j]))$ . Since the  $k\text{-ct}_i$  encrypts  $\text{WKEnc.sk}_i \neq \text{WKEnc.sk}_S$ , by the wrong-key decryption (Def 3),  $C_{i,j}^{id}$  encrypts a random bit  $\in \{0, 1\}$  and therefore  $C_i^{id}$  is an encryption of a random bit vector.
2. Compute  $C_i^{\text{preflag}} = (C_{i,1}^{\text{preflag}}, \dots, C_{i,\lambda}^{\text{preflag}})$  where  $C_{i,j}^{\text{preflag}} = \text{FHE.Eval}(\text{FHE.pk}_i \oplus (\overline{\text{WKEnc.pk}_i[j]}, C_{i,j}^{id}))$  for  $j \in [\lambda]$ . Since  $C_{i,j}^{id}$  encrypts a random bit  $b$ , with high probability the bit encrypted in  $C_{i,j}^{id} \neq \text{WKEnc.pk}_i[j]$  for all  $j \in [\lambda]$ . Therefore  $C_i^{\text{preflag}}$  is an encryption of a random bit vector, except with negligible probability.
3. Compute  $C_i^{\text{flag}} = \text{FHE.Eval}(\text{FHE.pk}_i, \times, (C_{i,1}^{\text{preflag}}, \dots, C_{i,\lambda}^{\text{preflag}}))$ . Since  $C_i^{\text{preflag}}$  is a random vector, with high probability there is atleast  $j$  s.t.  $C_{i,j}^{\text{preflag}}$  encrypts 0. Therefore,  $C_i^{\text{flag}}$  is an encryption of 0 except with negligible probability.

4. Compute  $\mathbf{C}_i^x = (C_{i,1}^x, \dots, C_{i,\mu}^x)$  where  $C_{i,j}^x = \text{FHE.Eval}(\text{FHE.pk}_i, \text{WKEnc.Dec}, (\text{k-ct}_i, \mathbf{C}_D[j]))$ . Since the  $\text{k-ct}_i$  encrypts  $\text{WKEnc.sk}_i \neq \text{WKEnc.sk}_S$ , by the wrong-key decryption (Def 3),  $C_{i,j}^x$  encrypts a random bit  $\in \{0, 1\}$  and therefore  $\mathbf{C}_i^x$  is an encryption of a random bit vector.
5. Compute  $\mathbf{C}_i^{\text{upd}} = (C_{i,1}^{\text{upd}}, \dots, C_{i,\mu}^{\text{upd}})$ , where  $C_{i,j}^{\text{upd}} = \text{FHE.Eval}(\text{FHE.pk}_i, \times, (C_{i,j}^x, C_{\text{flag}}))$ . Since  $C_{\text{flag}}$  is an encryption of 0,  $C_{i,j}^{\text{upd}}$  is an encryption of 0.
6. Update  $\mathbf{C}_i = (C_{i,1}, \dots, C_{i,\mu})$  as  $\text{FHE.Eval}(\text{FHE.pk}_i, -, (C_{i,j}, C_{i,j}^{\text{upd}}))$  for  $j \in [\mu]$ . Since  $C_{i,j}^{\text{upd}}$  is an encryption of 0, the value encrypted in  $C_{i,j}$  does not change.

**Case 2:**  $\text{UpdateCiphertext}(\mathcal{T}_{\text{privAccounts}}[\text{PK}_i], (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi), \text{PK}_i)$  is executed when  $\mathbf{C}_S$  corresponds to an encryption of  $\text{WKEnc.pk}_i$ . Let  $\mathbf{C}_S = \text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_j)$  where  $b_j = \text{WKEnc.pk}_S[j]$  for  $j \in [\lambda]$ .

$\text{UpdateCiphertext}$  works as follows:

1. Compute  $\mathbf{C}_i^{\text{id}} = (C_{i,1}^{\text{id}}, \dots, C_{i,\lambda}^{\text{id}})$ , where  $C_{i,j}^{\text{id}} = \text{FHE.Eval}(\text{FHE.pk}_i, \text{WKEnc.Dec}, (\text{k-ct}_i, \mathbf{C}_S[j]))$ . Since the  $\text{k-ct}_i$  encrypts  $\text{WKEnc.sk}_i = \text{WKEnc.sk}_S$ ,  $C_{i,j}^{\text{id}}$  encrypts a bit  $b_j \in \{0, 1\}$  such that  $\sum_{j=1}^{\lambda} b_j \times 2^j = \text{WKEnc.pk}_i$ .
2. Compute  $\mathbf{C}_i^{\text{preflag}} = (C_{i,1}^{\text{preflag}}, \dots, C_{i,\lambda}^{\text{preflag}})$  where  $C_{i,j}^{\text{preflag}} = \text{FHE.Eval}(\text{FHE.pk}_i, \oplus, (\overline{\text{WKEnc.pk}_i[j]}, \mathbf{C}_i^{\text{id}}))$  for  $j \in [\lambda]$ . Since  $C_{i,j}^{\text{id}}$  encrypts a bit  $b = \text{WKEnc.pk}_i[j]$ ,  $\mathbf{C}_i^{\text{preflag}}$  is an encryption of a vector with all 1s.
3. Compute  $C_i^{\text{flag}} = \text{FHE.Eval}(\text{FHE.pk}_i, \times, (C_{i,1}^{\text{preflag}}, \dots, C_{i,\lambda}^{\text{preflag}}))$ . Since  $\mathbf{C}_i^{\text{preflag}}$  is a vector of all 1s,  $C_i^{\text{flag}}$  is an encryption of 1.
4. Compute  $\mathbf{C}_i^x = (C_{i,1}^x, \dots, C_{i,\mu}^x)$  where  $C_{i,j}^x = \text{FHE.Eval}(\text{FHE.pk}_i, \text{WKEnc.Dec}, (\text{k-ct}_i, \mathbf{C}_D[j]))$ . Since the  $\text{k-ct}_i$  encrypts  $\text{WKEnc.sk}_i = \text{WKEnc.sk}_S$ ,  $C_{i,j}^x$  encrypts a bit  $b_j \in \{0, 1\}$  such that  $\sum_{j=1}^{\mu} b_j \times 2^j = x$ .
5. Compute  $\mathbf{C}_i^{\text{upd}} = (C_{i,1}^{\text{upd}}, \dots, C_{i,\mu}^{\text{upd}})$ , where  $C_{i,j}^{\text{upd}} = \text{FHE.Eval}(\text{FHE.pk}_i, \times, (C_{i,j}^x, C_{\text{flag}}))$ . Since  $C_{\text{flag}}$  is an encryption of 1,  $C_{i,j}^{\text{upd}}$  is an encryption of a bit  $b_j \in \{0, 1\}$  such that  $\sum_{j=1}^{\mu} b_j \times 2^j = x$ .
6. Update  $\mathbf{C}_i = (C_{i,1}, \dots, C_{i,\mu})$  as  $\text{FHE.Eval}(\text{FHE.pk}_i, -, (C_{i,j}, C_{i,j}^{\text{upd}}))$  for  $j \in [\mu]$ . Since  $C_{i,j}^{\text{upd}}$  is an encryption of  $b_j \in \{0, 1\}$  such that  $\sum_{j=1}^{\mu} b_j \times 2^j = x$ , the  $C_{i,1}$  is updated with  $x$  added to the balance.

Since the state is updated correctly in the both cases, we conclude our proof of correctness.

## B The private ledger functionality - $\mathcal{G}_{\text{PL}}$

### B.1 The ideal functionality

$\mathcal{G}_{\text{PL}}$  is parameterized by seven algorithms, `Validate`, `ExtendPolicy`, `blockify`, `Lkg`, `BlindTx`, `Blind` and `predict-time`, along with three parameters: `windowSize`, `Delay`  $\in \mathbb{N}$  and  $\mathcal{T}_1 = \{(P_1, v_1), \dots, (P_n, v_n)\}$ . These parameters are publicly known. The functionality manages variables `state`, `NxtBC`, `buffer`,  $\tau_L$  and  $\tau_{\text{state}}$ . The variables are initialized as follows: `state` :=  $\tau_{\text{state}}$  := `NxtBC` := `ids` :=  $\varepsilon$ , `buffer` :=  $\emptyset$ ,  $\tau_L = 0$ .

The functionality maintains the set of registered parties  $\mathcal{P}$ , the (sub-)set of honest parties  $\mathcal{H} \subseteq \mathcal{P}$ , and the subset of de-synchronized honest parties  $\mathcal{P}_{DS} \subset \mathcal{H}$ . The sets  $\mathcal{P}, \mathcal{H}, \mathcal{P}_{DS}$  are all initially set to  $\emptyset$ . When a new honest party is registered at the ledger, if it is registered with the clock and the global RO already, then it is added to the party sets  $\mathcal{H}$  and  $\mathcal{P}$  and the current time of the registration is also recorded; if the current time is  $\tau_L > 0$  it is also added to  $\mathcal{P}_{DS}$ . Similarly, when a party is de-registered, it is removed from  $\mathcal{P}$ . The ledger maintains the invariant that it is registered (as a functionality) to the clock whenever  $\mathcal{H} \neq \emptyset$ . Finally, during registration, the adversary is informed that a registration has occurred. The adversary responds with an ID and  $P_i$  is replaced with the resulting ID in  $\mathcal{T}_1$ . Further, the registration procedure returns ID.

For each party  $P_i \in \mathcal{P}$  the functionality maintains a pointer  $\text{pt}_p$  (initially set to 1) and a current-state view  $\text{state}_p := \varepsilon$  (initially set to empty). We refer to the vector  $\text{pt}_1, \dots, \text{pt}_n$  as  $\text{pt}$ .

*Handling initial parties:* If during the round  $\tau = 0$ , the ledger did not receive a registration from each initial party,  $(P_i, v_i) \in \mathcal{T}_1$ , the functionality halts.

*Upon receiving any input*  $I$  from any party or from the adversary, send `(CLOCK-READ, sidC)` to  $\mathcal{G}_{\text{clock}}$ ; upon receiving response `(CLOCK-READ, sidC,  $\tau$ )` set  $\tau_L := \tau$  and do the following if  $\tau > 0$  (otherwise, ignore input):

1. Let  $\hat{\mathcal{P}} \subseteq \mathcal{P}_{DS}$  denote the set of de-synchronized honest parties that have been registered (continuously) since time  $\tau' < \tau_L - \text{Delay}$ . Set  $\mathcal{P}_{DS} := \mathcal{P}_{DS} \setminus \hat{\mathcal{P}}$ .
2. If  $I$  was received from an honest party  $P_i \in \mathcal{P}$ :
  - (a) If  $I = (\text{SUBMIT}, \text{sid}, \text{tx})$ , set  $\mathcal{I}_H^T := \mathcal{I}_H^T \parallel ((\text{SUBMIT}, \text{sid}, \text{BlindTx}_A(\text{state}, \mathcal{P} \setminus \mathcal{H}, \text{ids}, \text{tx})), P_i, \tau_L)$ ; else set  $\mathcal{I}_H^T := \mathcal{I}_H^T \parallel (I, P_i, \tau_L)$
3. Compute  $\mathbf{N} = (\mathbf{N}_1, \dots, \mathbf{N}_\ell) := \text{ExtendPolicy}(\mathcal{I}_H^T, \text{state}, \text{NxtBC}, \text{buffer}, \tau_{\text{state}})$  and if  $\mathbf{N} \neq \varepsilon$  set `state` := `state`  $\parallel$  `blockify`( $\mathbf{N}_1$ )  $\parallel \dots \parallel$  `blockify`( $\mathbf{N}_\ell$ ) and  $\tau_{\text{state}} := \tau_{\text{state}} \parallel \tau_L^\ell$  where  $\tau_L^\ell := \tau_L \parallel \dots \parallel \tau_L$ .
4. For each `BTX`  $\in$  `buffer`: if `Validate`(`BTX`, `state`, `buffer`, `pt`,  $\mathcal{H}$ , `ids`) = 0 then delete `tx` from `buffer`. Also reset `NxtBC` :=  $\varepsilon$ .
5. If there exists  $P_i \in \mathcal{H} \setminus \mathcal{P}_{DS}$  such that  $|\text{state}| - \text{pt}_j > \text{windowSize}$  or  $\text{pt}_j < |\text{state}_j|$ , then set  $\text{pt}_k := |\text{state}|$  for all  $P_k \in \mathcal{H} \setminus \mathcal{P}_{DS}$ .

**Fig. 16.** The  $\mathcal{G}_{\text{PL}}$  functionality - Part 1

3. If the calling party  $P_i$  is stalled (according to the definition above), then no further actions are taken. Otherwise, depending on the above input  $I$  and its sender's ID,  $\mathcal{G}_{\text{PL}}$  executes the corresponding code from the following list:
  - *Submitting a transaction:*  
 If  $I = (\text{SUBMIT}, \text{sid}, \text{tx})$  and is received from a party  $P_i \in \mathcal{P}$  or from  $\mathcal{A}$  (on behalf of a corrupted party  $P_i$ ) do the following
    - (a) Choose a unique transaction ID  $\text{txid}$  and set  $\text{BTX} := (\text{tx}, \text{txid}, \tau_L, P_i)$
    - (b) If  $\text{Validate}(\text{BTX}, \text{state}, \text{buffer}, \text{pt}, \mathcal{H}, \text{ids}) = 1$ , then  $\text{buffer} := \text{buffer} \cup \text{BTX}$
    - (c) Send  $(\text{SUBMIT}, \text{BlindTx}_{\mathcal{A}}(\text{state}, \mathcal{P} \setminus \mathcal{H}, \text{ids}, \text{BTX}))$  to  $\mathcal{A}$
  - *Generating IDs*
  - *Reading the state*  
 If  $I = (\text{READ}, \text{sid})$  is received from a party  $P_i \in \mathcal{P}$ , then set  $\text{state}_i := \text{state}_i|_{\min\{\text{pt}_i, |\text{state}|\}}$  and return  $(\text{READ}, \text{sid}, \text{Blind}(\{P_i\}, \text{ids}, \text{state}_i))$  to the requestor. If the requestor is  $\mathcal{A}$  then send  $(\text{Blind}_{\mathcal{A}}(\mathcal{P} \setminus \mathcal{H}, \text{ids}, \text{state}), \text{map}(\text{BlindTx}_{\mathcal{A}}(\text{state}, \mathcal{P} \setminus \mathcal{H}), \text{ids}, \text{buffer}), \text{Lkg}(\text{state}, \text{buffer}, \tau_L), \mathcal{I}_H^T)$  to  $\mathcal{A}$
  - *Maintaining the ledger state:*  
 If  $I = (\text{MAINTAIN-LEDGER}, \text{sid})$  is received by an honest party  $P_i \in \mathcal{P}$  and (after updating  $\mathcal{I}_H^T$  as above)  $\text{predict-time}(\mathcal{I}_H^T) = \hat{\tau} > \tau_L$  then send  $\text{CLOCK-UPDATE}, \text{sid}_C$  to  $\mathcal{G}_{\text{clock}}$ . Else send  $I$  to  $\mathcal{A}$ .
  - *The adversary proposing the next block:*  
 If  $I = (\text{NEXT-BLOCK}, \text{hFlag}, (\text{txid}_1, \dots, \text{txid}_\ell))$  is sent from the adversary update  $\text{NxtBC}$  as follows:
    - (a) Set  $\text{listOfTxid} \leftarrow \varepsilon$
    - (b) For  $i = 1, \dots, \ell$  do: if there exists  $\text{BTX} := (x, \text{txid}, \tau_L, P_i) \in \text{buffer}$  with ID  $\text{txid} = \text{txid}_i$  then set  $\text{listOfTxid} := \text{listOfTxid} \parallel \text{txid}_i$ .
    - (c) Finally set  $\text{NxtBC} := \text{NxtBC} \parallel (\text{hFlag}, \text{listOfTxid})$  and output  $(\text{NEXT-BLOCK}, \text{ok})$  to  $\mathcal{A}$
  - *The adversary setting state-slackness:*  
 If  $I = (\text{SET-SLACK}, (P_i, \hat{\text{pt}}_i), \dots, (P_\ell, \hat{\text{pt}}_\ell))$  with  $\{P_i, \dots, P_\ell\} \subseteq \mathcal{H} \setminus \mathcal{P}_{DS}$  is received from the adversary  $\mathcal{A}$  do the following:
    - (a) If for all  $j \in [\ell] : |\text{state}| - \hat{\text{pt}}_j \leq \text{windowSize}$  and  $\hat{\text{pt}}_j \geq |\text{state}_j|$ , set  $\text{pt}_i = \hat{\text{pt}}_i$  for every  $j \in [i, \ell]$  and return  $(\text{SET-SLACK}, \text{ok})$  to  $\mathcal{A}$ .
    - (b) Otherwise set  $\text{pt}_j := |\text{state}|$  for all  $j \in [i, \ell]$ .
  - *The adversary setting the state for desynchronized parties:*  
 If  $I = (\text{DESYNC-STATE}, (P_i, \text{state}'_i), \dots, (P_\ell, \text{state}'_\ell))$  with  $(P_i, \dots, P_\ell) \subseteq \mathcal{P}_{DS}$  is received from the adversary  $\mathcal{A}$ , set  $\text{state}_j := \text{state}'_j$  for each  $j \in [i, \ell]$  and return  $(\text{DESYNC-STATE}, \text{ok})$  to  $\mathcal{A}$ .

Fig. 17. The  $\mathcal{G}_{\text{PL}}$  functionality - Part 2

Function  $\text{Validate}(\text{BTX}, \text{state}, \text{buffer}, \mathcal{H}, \text{ids})$ :

1. Parse  $\text{BTX}$  as  $(\text{tx}, \text{txid}, \tau_L, P_i)$
2. Let  $ep^*$  be the epoch corresponding to  $\tau_L$ , and the current epoch be  $ep$ . Check that  $ep^* = ep$
3. Parse  $\text{tx}$  as  $(P_i, P_j, v)$  where  $P_i, P_j \in \text{ids}$
4. Check that  $v_i > v$
5. Let  $\tau_{ep}$  be the time when the current epoch starts.
6. Check that there exists no  $\text{BTX}' \in \{\text{state}, \text{buffer}\}$  after time  $\tau_{ep}$  from party  $P_i$ .
7. If any of the above checks return false, return 0, else return 1.

Fig. 18. Ideal Validation Predicate

Let  $\text{tx} = (\text{stx}_1, \dots, \text{stx}_\ell)$ , where  $\text{stx} = (\text{pk}_r, x)$   
 Function  $\text{BlindSTx}(\text{state}, \mathcal{P}, \text{ids}, (\text{pk}, \text{stx}))$

1. Let  $b \leftarrow 0$
2. If  $\text{stx} = (\text{pk}_r, x)$  and  $\text{pk}_r \in \mathcal{P} \setminus \mathcal{H}$ , set  $b \leftarrow 1$
3. If  $\text{pk} \neq \text{MINT} \vee \text{pk}$  not owned by  $P_i \in \mathcal{P}$ , set  $b \leftarrow 0$
4. If  $b$ , return  $(\text{pk}, \text{stx})$ , else return  $(\perp, |\text{stx}|)$

Now,  
 $\text{BlindTx}(\text{state}, \mathcal{P}, \text{ids}, (\text{tx}, \text{txid}, \cdot, \cdot)) = (\text{map}(\text{BlindSTx}(\text{state}, \mathcal{P}, \text{ids}), \text{tx}), \text{txid})$   
 $\text{BlindTx}_A(\text{state}, \mathcal{P}, \text{ids}, (\text{tx}, \text{txid}, \tau_L, P_s)) = (\text{map}(\text{BlindSTx}(\text{state}, \mathcal{P}, \text{ids}), \text{tx}), \text{txid}, \tau_L, P_s)$

**Fig. 19.** Blinding function

This function is the same as the one defined in Ouroboros Genesis [6]. We present an overview below:

1. Create an honest client block as an alternative  $\mathbf{N}_{df}$ .
2. Parse the block proposed by the adversary:
  - Check if upon adding a transaction from the block invalidates the rest of the transactions in the block.
  - If yes, return  $\mathbf{N}_{df}$ .
  - If the proposed block is proposed on behalf of an honest party and there exist *old enough* valid transactions in the buffer of any other honest party set a flag  $\text{oldValidTxMissing} \leftarrow \text{true}$  and return  $\mathbf{N}_{df}$
  - If there are too many adversarially generated blocks return  $\mathbf{N}_{df}$
  - If a sequence of blocks takes too much time to be proposed, return  $\mathbf{N}_{df}$
  - Else update the state with the newly proposed block.

**Fig. 20.** Extend Policy function

## B.2 Additional UC protocols

### Protocol $\text{ReadState}(\text{sid}, \mathcal{C}_{\text{loc}}, P_i)$

1. Execute **FetchInformation** to receive the newest messages for this round; denote the output chains by  $\mathcal{C}_1, \dots, \mathcal{C}_M$
2. Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
3. Let  $\mathcal{N} \leftarrow \{\mathcal{C}_1, \dots, \mathcal{C}_M\}$
4. Invoke protocol **SelectChain**( $\mathcal{N}, \dots$ ) (as defined in Ouroboros Genesis [6]) and receive an updated  $\mathcal{C}_{\text{loc}}$
5. Extract the list of transactions  $\text{st}$  from the current local chain  $\mathcal{C}_{\text{loc}}$ .
6. Set  $\text{st}_{\text{ideal}} = \emptyset$
7. For each  $\text{tx}$  in  $\text{st}^{\lceil k}$ 
  - If  $\text{tx} = \text{TRANSFER}$  and  $\text{Dec}(\text{WKEnc.sk}_i, \mathbf{C}_{\mathbf{R}}) = \text{WKEnc.pk}_i$  then decrypt  $\mathbf{C}_{\mathbf{R}} = v$  and record  $(\text{TRANSFER}, v)$  as  $\text{st}_{\text{ideal}} = \text{st}_{\text{ideal}} \parallel (\text{TRANSFER}, v)$
  - If  $\text{tx} = \text{MINT}$  and is equal to  $(\text{PK}_i, v, \text{rt}, \sigma)$ , record  $(\text{MINT}, v)$  as  $\text{st}_{\text{ideal}} = \text{st}_{\text{ideal}} \parallel (\text{MINT}, v)$
8. Return  $\text{st}_{\text{ideal}}$

**Fig. 21.** Read State

### Function $\text{ValidTx}(\text{tx}_i, \{\mathcal{T}\}_{ep}, \mathcal{C}_{\text{loc}})$

If  $\text{tx} = \text{TRANSFER}$

1. Let  $ep$  be the current epoch and  $\{\mathcal{T}\}_{ep}$  be the set of states in the current epoch.
2. Parse  $\text{tx}$  as  $(\mathbf{C}_{\mathbf{S}}, \mathbf{C}_{\mathbf{R}}, \mathbf{C}_{\mathbf{D}}, \mathbf{C}_{\mathbf{C}}, \text{PRFOut}, \pi)$
3. Verify that  $\text{rt}_{\mathcal{T}} = \text{MerkleCRH}(\mathcal{T})$  for atleast one of  $\mathcal{T}$  in  $\{\mathcal{T}\}_{ep}$ . Else abort.
4. Run  $\text{Verify}(\text{zk.vk}, x, \text{Proof})$  where  $x = (\text{rt}_{\mathcal{T}}, \mathbf{C}_{\mathbf{S}}, \mathbf{C}_{\mathbf{R}}, \mathbf{C}_{\mathbf{D}}, \mathbf{C}_{\mathbf{C}})$  and  $\text{Proof} = \pi$
5. Verify that  $\text{PRFOut}$  does not already appear in the buffer and  $\mathcal{C}_{\text{loc}}$  after slot  $ep * R$ .
6. If any of the checks above fail return 0, else return 1.

If  $\text{tx} = \text{MINT}$

1. Parse  $\text{tx}$  as  $(\text{PK}_i, x, \text{rt}_{\text{pubAccounts}}, \sigma)$
2. Check that  $\mathcal{T}_{\text{pubAccounts}}[\text{PK}_i] > x$
3. Check that  $\text{Verify}(\text{vk}_i, (\text{PK}_i, x, \text{rt}_{\text{pubAccounts}}), \sigma) = 1$
4. If any of these checks fail, output 0, else output 1.

**Fig. 22.** Real world validation

## C Hybrid functionalities

The functionality  $\mathcal{F}_{\text{init}}$  is parameterized by the number of initial account-holders  $n$  and their respective balances  $b_1, \dots, b_n$ .  $\mathcal{F}_{\text{init}}$  interacts with  $P_1, \dots, P_n$  as follows:

- In the first round, upon a request from some account-holder  $P_i$  of the form  $(\text{claim}, \text{sid}, P_i, \text{PK}_i)$ , the functionality computes  $\text{REGISTRATION}(\text{PK}_i)$ .
- Once all parties have registered, it samples and stores a random value  $\eta_1 \leftarrow_{\$} \{0, 1\}^\lambda$ . it then constructs a genesis block  $(\mathbb{C}, \eta_1)$ , where  $\mathbb{C} = (\mathbf{C}_1, \text{PK}_n), \dots, (\mathbf{C}_n, \text{PK}_n)$

If this is not the first round then do the following:

- If any of the account-holders did not send a request of the above form in the genesis round, then  $\mathcal{F}_{\text{init}}$  outputs an error and halts.
- Otherwise, if the currently received input is a request of the form  $(\text{gen-req}, \text{sid}, P_i)$  from any account-holder  $P_i$ , then  $\mathcal{F}_{\text{init}}$  sends  $(\text{gen-block}, \text{sid}, (\mathbb{C}, \eta_1))$  to  $P_i$ .

**Fig. 23.**  $\mathcal{F}_{\text{init}}$  functionality

The functionality maintains the set  $\mathcal{P}$  of registered identities that is parties  $P_i = (\text{sid}, \text{pid})$ . It also manages the set  $F$  of functionalities. Initially  $\mathcal{P} = \emptyset$  and  $F = \emptyset$ .

For each session  $\text{sid}$  the clock maintains a variable  $\tau_{\text{sid}}$ . For each identity  $P_i = (\text{pid}, \text{sid}) \in \mathcal{P}$  it manages variable  $d_{P_i}$ . For each pair  $(\mathcal{F}, \text{sid}) \in F$  it manages a variable  $d_{(\mathcal{F}, \text{sid})}$  all initialized to 0.

*Synchronization :*

- Upon receiving  $(\text{CLOCK-UPDATE}, \text{sid}_C)$  from some party  $P_i \in \mathcal{P}$  set  $d_{P_i} := 1$ ; execute **Round-Update** and forward  $(\text{CLOCK-UPDATE}, \text{sid}, P_i)$  to  $\mathcal{A}$
- Upon receiving  $(\text{CLOCK-UPDATE}, \text{sid}_C)$  from some functionality  $\mathcal{F} \in F$  set  $d_{(\mathcal{F}, \text{sid})} := 1$ ; execute **Round-Update** and forward  $(\text{CLOCK-UPDATE}, \text{sid}, \mathcal{F})$  to this instance of  $\mathcal{F}$ .
- Upon receiving  $(\text{CLOCK-READ}, \text{sid}_C)$  from any participant return  $(\text{CLOCK-READ}, \text{sid}_C, \tau)$  to the requester.

*Procedure Round-Update :* For each session  $\text{sid}$  do: If  $d_{(\mathcal{F}, \text{sid})} := 1$  for all  $\mathcal{F} \in F$  and  $d_{P_i} = 1$  for all honest parties  $P_i = (\cdot, \text{sid}) \in \mathcal{P}$  then set  $\tau_{\text{sid}} := \tau_{\text{sid}} + 1$  and reset  $d_{(\mathcal{F}, \text{sid})} := 0$  and  $d_{P_i} := 0$  for all parties  $P_i = (\cdot, \text{sid}) \in \mathcal{P}$ .

**Fig. 24.**  $\mathcal{G}_{\text{clock}}$  functionality

The non-interactive zero-knowledge functionality  $\mathcal{F}_{\text{nizk}}^{\mathcal{L}}$  allows proving of statements in an NP language  $\mathcal{L}$ . It maintains a set of statement/proof pairs  $\Pi$ , initialized to  $\emptyset$ .

*Proving* Upon receiving a message  $(\text{Prove}, \text{sid}, x, w)$ :

1. If  $(x, w) \notin \mathcal{L}$  then return  $(\text{proof}, \text{sid}, x, \perp)$
2. Else send  $(\text{Prove}, \text{sid}, x)$  to  $\mathcal{A}$  and receive the reply  $(\text{proof}, \text{sid}, x, \pi)$ . Do  $\Pi = \Pi \cup \{(x, \pi)\}$  and return  $(\text{proof}, \text{sid}, x, \pi)$

*Proof Verification* When receiving a message  $(\text{verify}, \text{sid}, x, \pi)$  :

1. If  $(x, \pi) \notin \Pi$  then send  $(\text{verify}, \text{sid}, x, \pi)$  to  $\mathcal{A}$  and then receive the reply  $R$ .
2. If  $R = (\text{witness}, \text{sid}, x, \pi, w) \wedge (x, w) \in \mathcal{L}$  then let  $\Pi = \Pi \cup (x, \pi)$ .
3. Return  $(\text{verify}, \text{sid}, x, \pi, (x, \pi) \in \Pi)$

**Fig. 25.**  $\mathcal{F}_{\text{nizk}}$  functionality

The ideal functionality is parameterized by an **Eligible** predicate and maintains the following elements: (1) a global set of participants  $\mathcal{P} = (P_1, b_1), \dots, (P_n, b_n)$  (2) A table  $T$  which has one row per party and column for each  $\text{tag} \in [\mathbb{N}]$  given by parties when checking eligibility. The table stores the eligibility information of each party in each  $\text{tag}$ . (3) A list  $\mathcal{L}$  to store a proof  $\pi$  corresponding to a message  $\text{msg}$  in some  $\text{tag}$

*Check Eligibility* Upon receiving  $(\text{ELIGIBILITY-CHECK}, \text{sid}, \text{tag})$  from a party  $P_i$  do the following:

1. If  $P_i \in \mathcal{P}$  and  $T(P_i, \text{tag})$  is undefined, sample  $r \in \{0, 1\}^\ell$ , run  $\text{Eligible}(P_i, r, \text{tag})$  to get  $b \in \{0, 1\}$ . Set  $T(P_i, \text{tag}) = b$
2. Output  $(\text{ELIGIBILITY-CHECK}, \text{sid}, T(P_i, \text{tag}))$  to  $P_i$ .

*Proof of eligibility* Upon receiving  $(\text{CREATE-PROOF}, \text{sid}, \text{tag}, \text{msg})$  from some party  $P_i$ :

1. If  $T(P_i, \text{tag}) = 1$ , send  $(\text{PROVE}, \text{tag}, \text{msg})$  to  $\mathcal{A}$ . Else send  $(\text{DECLINED}, \text{tag}, \text{msg})$  to  $P_i$ .
2. Upon receiving  $(\text{DONE}, \psi, \text{tag}, \text{msg})$  from  $\mathcal{A}$ , set  $\pi := \psi$  and record  $(\pi, \text{tag}, \text{msg})$  in  $\mathcal{L}$ . Send  $(\text{CREATE-PROOF}, \pi, \text{tag}, \text{msg})$  to  $P_i$ .

*Verifying proofs* Upon receiving  $(\text{VERIFY}, \text{sid}, \pi, \text{tag}, \text{msg})$  from some party  $P'$ :

1. If  $(\pi, \text{tag}, \text{msg}) \in \mathcal{L}$  output  $(\text{VERIFIED}, \text{sid}, (\pi, \text{tag}, \text{msg}), 1)$  to  $P'$
2. If  $(\pi, \text{tag}, \text{msg}) \notin \mathcal{L}$  send  $(\text{VERIFY}, \text{sid}, (\pi, \text{tag}, \text{msg}))$  to  $\mathcal{A}$  and wait for a witness  $w$  from the adversary  $\mathcal{A}$ . Check if  $w$  is valid as follows:
  - Parse  $w = (P_i, \text{tag}, \text{msg})$  and check that  $T(P_i, \text{tag}) = 1$
  - If yes, store  $(\pi, \text{tag}, \text{msg})$  in the list  $\mathcal{L}$  and send  $(\text{VERIFIED}, \text{sid}, (\pi, \text{tag}, \text{msg}), 1)$  to  $P'$
 If either of these checks are false, output  $(\text{VERIFIED}, \text{sid}, (\pi, \text{tag}, \text{msg}), 0)$  to  $P'$ .

**Fig. 26.**  $\mathcal{F}_{\text{anon-selection}}$  functionality of [9]

## D Security Proof

### D.1 Simulator

The simulator internally emulates the hybrid functionalities  $\mathcal{F}_{\text{init}}$ ,  $\mathcal{F}_{\text{nizk}}$ ,  $\mathcal{F}_{\text{anon-selection}}$  and relays any communication between  $\mathcal{A}$  (on behalf of corrupted party) and the emulated functionality.

*Simulation of  $\mathcal{F}_{\text{init}}$  towards  $\mathcal{A}$*

1. Upon receiving  $(\text{claim}, \text{sid}, P_i, \text{PK}_i)$  from  $\mathcal{A}$ , send  $(\text{REGISTER}, \text{sid})$  on behalf of  $P_i$  to  $\mathcal{G}_{\text{PL}}$ .
2. The functionality updates the state of the blockchain by running  $\text{REGISTRATION}(\mathcal{T} \parallel \text{PK}_i)$ .

*Simulation of  $\mathcal{F}_{\text{nizk}}$  towards  $\mathcal{A}$*

1. The simulator maintains a set of statement, witness and proof pairs for the relation  $\mathcal{R}_{\text{TRANSFER}}$  in  $\Pi_{\text{TRANSFER}}$  and for the relation  $\mathcal{R}_{\text{KEYGEN}}$  in  $\Pi_{\text{KEYGEN}}$ .
2. Upon receiving a message  $(\text{Prove}, \text{sid}, x, w)$  from some corrupted  $P_i$ , check if  $(x, w) \in \mathcal{L}$ . If not respond with  $\perp$ , else send  $(\text{Prove}, \text{sid}, x)$  to  $\mathcal{A}$  and receive back  $(\text{proof}, \text{sid}, x, \pi)$ . Record  $(\pi, x, w) \in \Pi_{\text{TRANSFER}}$  (or  $\Pi_{\text{KEYGEN}}$ ) and return  $(\text{proof}, \text{sid}, x, \pi)$  to the corrupted party.
3. Upon receiving a message  $(\text{verify}, \text{sid}, x, \pi)$  from a corrupt party, check if  $(x, *, \pi) \in \Pi_{\text{TRANSFER}}$  (or  $\Pi_{\text{KEYGEN}}$ ). If yes, return  $(\text{verify}, \text{sid}, x, \pi, 1)$  to the corrupted party. If  $(x, *, \pi) \notin \Pi_{\text{TRANSFER}}$  or  $\Pi_{\text{KEYGEN}}$ , send  $(\text{verify}, \text{sid}, x, \pi)$  to  $\mathcal{A}$  and receive back a reply  $R$ . If  $R = (\text{witness}, \text{sid}, x, \pi, w)$  and  $(x, w) \in \mathcal{L}$ , then update  $\Pi_{\text{TRANSFER}} = \Pi_{\text{TRANSFER}} \cup (x, w, \pi)$  or  $\Pi_{\text{KEYGEN}} = \Pi_{\text{KEYGEN}} \cup (x, w, \pi)$  depending on the relation of the proof, and return  $(\text{verify}, \text{sid}, x, \pi, 1)$ , else respond with  $(\text{verify}, \text{sid}, x, \pi, 0)$  to the corrupted party.

*Simulation of  $\mathcal{F}_{\text{anon-selection}}$  towards  $\mathcal{A}$*

1. Upon receiving  $(\text{ELIGIBILITY-CHECK}, (sl, ep))$  from a corrupt party, sample a random  $r \in \{0, 1\}^\ell$  and run  $\text{Eligible}(P_i, r, (sl, ep))$  to get  $b \in \{0, 1\}$ . Return  $(\text{ELIGIBILITY-CHECK}, (sl, ep), b)$  to the corrupt party. And store  $T(P_i, (sl, ep)) = 1$
2. Upon receiving  $(\text{CREATE-PROOF}, \text{sid}, (sl, ep), msg)$ , from a corrupt party  $P_i$ , check that  $T(P_i, (sl, ep)) = 1$  and if yes, forward the request to the adversary and receive  $\Psi$ . Record  $(\Psi, (ep, sl), msg)$  and return  $(\text{CREATE-PROOF}, \pi, (ep, sl), msg)$  to the corrupt party.
3. Upon receiving  $(\text{VERIFY}, \text{sid}, \pi, (ep, sl), msg)$  from a corrupt party  $P_i$ , check if  $(\pi, (ep, sl), msg)$  has been recorded, if yes return  $(\text{VERIFIED}, \text{sid}, (\pi, \text{tag}, msg), 1)$  to the party. Else send  $(\text{VERIFY}, \text{sid}, \pi, (ep, sl), msg)$  to the adversary and receive back a witness  $w$ . Parse  $w = (P_i, (sl, ep), msg)$  and check if  $T(P_i, (sl, ep)) = 1$ . If yes, record  $(\pi, (ep, sl), msg)$  and send  $(\text{VERIFIED}, \text{sid}, (\pi, \text{tag}, msg), 1)$  to  $P_i$ , else send  $(\text{VERIFIED}, \text{sid}, (\pi, \text{tag}, msg), 0)$  to  $P_i$ .

**Fig. 27.** Simulation of hybrid functionalities towards the adversary

*Simulation of  $\mathcal{F}_{N-MC}$*  The simulation is similar to that of Ouroboros Genesis [6]. We present below the additional changes to the simulation.

1. Upon receiving  $(\text{MULTICAST}, (\text{tx}_{i_1}, P_{i_1}), \dots, (\text{tx}_{i_\ell}, P_{i_\ell}))$  with list of transactions from  $\mathcal{A}$  on behalf of some corrupted  $P_i$  do the following:

**SimulateAdvTransaction(tx)**

If tx is a TRANSFER transaction:

- (a) Parse tx as  $(\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$
- (b) Check that  $(\pi, (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_C, \mathbf{C}_D, \text{PRFOut}, \text{rt}_{\mathcal{T}_{\text{privAccounts}}}, ep), w)$  exists in  $\Pi_{\text{TRANSFER}}$  as was recorded by the simulation of  $\mathcal{F}_{\text{nizk}}$  towards the adversary. If such an entry does not exist, abort with **ZKSoundnessFailure**
- (c) If there exists an honestly simulated transaction with PRFOut equal to the one parsed from tx, abort with error **PRFFailure**
- (d) Else parse  $w$  as  $(\text{PK}_S, \text{SK}_S, \text{PK}_R, v, v_S, \mathbf{C}, \text{path})$ . If  $(\text{PK}_S, \mathbf{C}) \notin \mathcal{T}_{\text{privAccounts}}$  but  $\text{VerifyPath}(\text{rt}_{\mathcal{T}_{\text{privAccounts}}}, \text{path}) = 1$ , abort with **CRHFailure**.
- (e) Let  $\text{SK}_S = (\text{FHE.sk}_S, \text{WKEnc.sk}_S, \text{sk}_S, k_S)$  and from  $\Pi_{\text{KEYGEN}}$ , find the record  $(\pi, \text{PK}_S, w^*)$  and let  $w = (\text{FHE.sk}_S, \text{WKEnc.sk}_S, \text{sk}_S, k_S^*)$ . If  $k_S^* \neq k_S$ , abort with error **CommFailure**.
- (f) Set  $\text{tx} = (\text{TRANSFER}, (\text{PK}_S, \text{PK}_R, x))$  and send  $(\text{SUBMIT}, \text{sid}, \text{tx})$  to  $\mathcal{G}_{\text{PL}}$  and receive back  $(\text{SUBMIT}, (\text{tx}, \text{txid}, \tau_L, P_S))$  from  $\mathcal{G}_{\text{PL}}$ . Record txid.

If tx is a MINT transaction:

- (a) Parse tx as  $(\text{tx}', \sigma)$  where  $\text{tx}' = (v, \text{PK}_i, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}})$
- (b) If  $\sigma$  corresponds to that of an honest party abort with **sigFailure**.
- (c) Else send  $(\text{SUBMIT}, \text{sid}, \text{tx} = (\text{MINT}, (\text{PK}_i, x)))$  to  $\mathcal{G}_{\text{PL}}$  and receive back  $(\text{SUBMIT}, (\text{tx}, \text{txid}, \tau_L, P_S))$  from  $\mathcal{G}_{\text{PL}}$ . Record txid.

2. Upon receiving  $(\text{MULTICAST}, \text{sid}, (\mathcal{C}_{i_1}, P_{i_1}), \dots, (\mathcal{C}_{i_\ell}, P_{i_\ell}))$

- (a) Let  $\mathcal{C}_i$  be the longest chain out of  $\mathcal{C}_{i_1}, \dots, \mathcal{C}_{i_\ell}$
- (b) Let  $\text{tx}_1, \dots, \text{tx}_n$  be transactions  $\notin \mathcal{C}_i^{\uparrow k}$ .
- (c) For each  $\text{tx}_i \in \{\text{tx}_1, \dots, \text{tx}_n\}$ 
  - i. Find recorded txid that corresponds to  $\text{tx}_i$ .
  - ii. If txid does not exist, run **SimulateAdvTransaction(tx)**
- (d) Run **EXTENDLEDGERSTATE**( $\tau$ ) as defined in [7]: which sends  $(\text{NEXT-BLOCK}, \text{hFlag}_j, \text{list}_j)$  to  $\mathcal{G}_{\text{PL}}$  and receive  $(\text{NEXT-BLOCK}, ok)$  as an immediate response. Here  $\text{list}_j$  is a list of txids that are not in the state but in  $\mathcal{C}_i^{\uparrow k}$  and  $\text{hFlag}_j$  denotes if the corresponding blocks were proposed by honest parties.

3. Upon receiving  $(\text{NEW-PARTY}, \text{sid}, P_i, \text{PK}_i, \pi_{\text{KEYGEN}})$  from a corrupt party,

- (a) Check if  $(\pi, \text{PK}_i, w)$  exists in  $\Pi_{\text{KEYGEN}}$  as was recorded by the simulation of  $\mathcal{F}_{\text{nizk}}$  towards the adversary. If such an entry does not exist, abort with **ZKSoundnessFailure**.
- (b) Else register with  $\mathcal{G}_{\text{PL}}$  on behalf of  $P_i$  and upon receiving a notification that a new party has registered, send  $\text{PK}_i$ .

**Fig. 28.** Simulation of network functionality towards  $\mathcal{A}$

*Generating keys* : Upon receiving registration request from the environment:

1. Generating keys:
  - $(\text{FHE.pk}_i, \text{FHE.sk}_i) \leftarrow \text{FHE.KeyGen}(1^\lambda)$
  - $(\text{WKEnc.pk}_i, \text{WKEnc.sk}_i) \leftarrow \text{FHE.KeyGen}(1^\lambda)$
  - $(\text{sk}_i, \text{vk}_i) \leftarrow \text{Sign.KeyGen}(1^\lambda)$
  - $k \leftarrow \text{PRF.KeyGen}(1^\lambda)$
2. Encrypting WKEnc keys:
  - $\text{k-ct}_i \leftarrow \{\text{FHE.Enc}(\text{FHE.pk}_i, 0)\}_{i=1}^\lambda$
3. Committing to the PRF key:
  - $\text{C}_{\text{PRF}} \leftarrow \text{Com}(0; r)$  where  $r \leftarrow \{0, 1\}^\lambda$
4. Return  $\text{PK}_i := (\text{k-ct}_i, \text{FHE.pk}_i, \text{WKEnc.pk}_i, \text{vk}_i, \text{C}_{\text{PRF}})$  and  $\text{SK}_i = (\text{FHE.sk}_i, \text{WKEnc.sk}_i, \text{sk}_i, k)$

*Submitting honest transactions* : Upon receiving (SUBMIT, tx) from the environment for honest transactions:

1. If tx is of the form (TRANSFER||tx')
  - (a) Let  $(\text{PK}^*, \text{SK}^*) \leftarrow \text{KEYGENERATION}(\lambda)$
  - (b) Set  $x = 0$
  - (c) Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
  - (d) Let  $\mathcal{C}_{\text{loc}}$  be the chain upto the beginning of the epoch  $ep$ .
  - (e) Let  $(\text{C}_S, \text{C}_R, \text{C}_D, \text{C}_C, \pi, \text{PRFOut}) := \text{TRANSFER}(\text{PK}^*, \text{PK}^*, x, ep, R, \mathcal{C}_{\text{loc}})$
  - (f) Sample  $y \leftarrow \{0, 1\}^\lambda$  and replace PRFOut with  $y$ .
  - (g) Submit (MULTICAST, tx) to  $\mathcal{F}_{\text{N-MC}}$
2. Else if tx is of the form (MINT, tx')
  - (a) Parse tx' as  $(\text{pk}_S, x)$
  - (b) Compute  $\text{tx} = \text{MINT}(v, \text{PK}_i, \text{SK}_i, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}})$
  - (c) Submit (MULTICAST, tx) to simulated  $\mathcal{F}_{\text{N-MC}}$ .

*Simulating leader election* : Upon receiving (MAINTAIN-LEDGER, sid), extract from  $\mathcal{I}_H^T$ , the party  $P_i$  that issued this query. If  $P_i$  has already completed the round task then ignore the request. Otherwise:

1. Let  $(ep, sl, ptr, h, B')$  be as defined in LotteryProcedure executed by  $P_i$ .
2. Send (CREATE-PROOF,  $(ep, sl), B$ ) to  $\mathcal{A}$  and receive back  $\pi$ .
3. Set  $\text{tx}_{\text{lead}} = ((ep, sl), \text{pt}, h, \pi)$  and broadcast  $(\text{tx}_{\text{lead}}, B')$  to  $\mathcal{F}_{\text{N-MC}}^{\text{bc}}$ .

**Fig. 29.** Simulating honest parties

**Theorem 1.**(restated) *The protocol  $\Pi_{\text{PriFHEte}} UC$  realizes the  $\mathcal{G}_{\text{PL}}$  functionality in the  $(\mathcal{G}_{\text{clock}}, \mathcal{F}_{\text{anon-selection}}, \mathcal{F}_{\text{init}}, \mathcal{F}_{\text{nizk}}, \mathcal{F}_{\text{N-MC}})$ -hybrid world, assuming key-private CPA secure encryption, CPA secure fully homomorphic encryption, secure pseudorandom functions, secure commitment schemes and unforgeable signature scheme.*

*Proof. Proof by hybrids* We prove security via a sequence of hybrids where we start from real world and move to the ideal world. The properties of the blockchain such as consistency, chain quality, liveness are handled by the ExtendPolicy algorithm. Since we do not modify this algorithm from the one defined in Ouroboros Genesis [6], these properties are achieved by our protocols as well. We therefore only consider the hybrids that correspond to the protocols on the transactional layer below:

- **Hybrid<sub>0</sub>**: The real world protocol.
- **Hybrid<sub>1</sub>**: This hybrid is the same as **Hybrid<sub>0</sub>**, except upon receiving a SUBMIT command, the zero knowledge proofs  $\pi$  by simulated zero knowledge proofs in the TRANSFER algorithm. By the zero knowledge property of the underlying NIZK scheme we have that the two hybrids are indistinguishable.

TRANSFER(PK<sub>S</sub>, SK<sub>S</sub>, PK<sub>R</sub>, x, ep, R, C<sub>loc</sub>) User  $P_i$  does:

1. ...
  9. Let  $x = \{\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \text{rt}_{\mathcal{T}}\}$ . Send (Prove, sid, x) to the  $\mathcal{A}$  and receive  $\pi$  (just as in  $\mathcal{F}_{\text{nik}}$  functionality).
  10. Return  $\text{tx} = (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$
- **Hybrid<sub>2</sub>**: This hybrid is the same as **Hybrid<sub>1</sub>**, except that upon receiving a SUBMIT command and PK<sub>R</sub> is honest, all ciphertexts  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C$  are replaced by encryptions to 0. By the CPA security of the underlying encryption scheme the two hybrids are indistinguishable.

TRANSFER(PK<sub>S</sub>, PK<sub>R</sub>, x, ep, R, C<sub>loc</sub>) User  $P_i$  does:

1. ...
  4. Encrypt sender's identity
    - For  $i \in [\lambda]$ , compute  $C_{S,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_i)$ , where  $b_i = 0$
    - $\mathbf{C}_S := (C_{S,1}, \dots, C_{S,\lambda})$
  5. Encrypt receiver's identity
    - For  $i \in [\lambda]$ , compute  $C_{R,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_R, b_i)$ , where  $b_i = 0$
    - $\mathbf{C}_R := (C_{R,1}, \dots, C_{R,\lambda})$
  6. Encrypt credited value
    - For  $i \in [\lambda]$ , compute  $C_{D,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_R, b_i)$ , where  $b_i = 0$
    - $\mathbf{C}_D := (C_{D,1}, \dots, C_{D,\lambda})$
  7. Encrypt debited value
    - For  $i \in [\lambda]$ , compute  $C_{C,i} = \text{WKEnc.Enc}(\text{WKEnc.pk}_S, b_i)$ , where  $b_i = 0$
    - $\mathbf{C}_C := (C_{C,1}, \dots, C_{C,\lambda})$
  8. Compute PRF output:
    - Compute  $(\text{PRFOut}) \leftarrow \text{PRF}(k, ep)$
  9. Let  $x = \{\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \text{rt}_{\mathcal{T}}\}$ . Send (Prove, sid, x) to the  $\mathcal{A}$  and receive  $\pi$  (just as in  $\mathcal{F}_{\text{nik}}$  functionality).
  10. Return  $\text{tx} = (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$
- We prove in Lemma 1 that the two hybrids are indistinguishable.
- **Hybrid<sub>3</sub>**: This hybrid is the same as **Hybrid<sub>2</sub>**, except that upon receiving a SUBMIT command, run  $(\text{WKEnc.pk}^*, \text{WKEnc.sk}^*) \leftarrow \text{WKEnc.KeyGen}(1^\lambda)$  and replace ciphertexts  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C$  with encryptions under  $\text{pk}^*$ . By the key-privacy property of the underlying encryption scheme the two hybrids are indistinguishable.

TRANSFER(PK<sub>S</sub>, PK<sub>R</sub>, x, ep, R, C<sub>loc</sub>) User  $P_i$  does:

1. Run  $(\text{PK}^*, \text{SK}^*) \leftarrow \text{KEYGENERATION}(\lambda)$
2. Let  $\text{PK}^* = (\text{k-ct}^*, \text{FHE.pk}^*, \text{WKEnc.pk}^*, \text{vk}^*, \text{C}_{\text{PRF}}^*)$
3. Set  $\text{WKEnc.pk}_S = \text{WKEnc.pk}^*$  and  $\text{WKEnc.pk}_R = \text{WKEnc.pk}^*$
4. ...
10. Return  $\text{tx} = (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi)$

We prove in Lemma 2 that the two hybrids are indistinguishable.

- **Hybrid<sub>4</sub>**: This hybrid is the same as **Hybrid<sub>3</sub>**, except that commitment to the PRF key  $k$  is replaced by a commitment to 0. By the commitment property of the underlying commitment scheme, the two hybrids are indistinguishable.

KEYGENERATION( $\lambda$ ): User  $P_i$  does:

1. Key Generation: ...
  - $(\text{FHE.pk}_i, \text{FHE.sk}_i) \leftarrow \text{FHE.KeyGen}(1^\lambda)$
  - $(\text{WKEnc.pk}_i, \text{WKEnc.sk}_i) \leftarrow \text{FHE.KeyGen}(1^\lambda)$
  - $(\text{sk}_i, \text{vk}_i) \leftarrow \text{Sign.KeyGen}(1^\lambda)$
  - $k \leftarrow \text{PRF.KeyGen}(1^\lambda)$
2. Encrypting WKEnc keys:

- $k\text{-ct}_i \leftarrow \text{FHE.Enc}(\text{FHE.pk}_i, \text{WKEnc}, \text{sk}_i[1]), \dots, \text{FHE.Enc}(\text{FHE.pk}_i, \text{WKEnc}, \text{sk}_i[\lambda])$
- 3. Committing to the PRF key:
  - $\mathbf{C}_{\text{PRF}} \leftarrow \text{Com}(0; r)$  where  $r \leftarrow \{0, 1\}^\lambda$ .
- 4. Return  $\text{PK}_i := (k\text{-ct}_i, \text{FHE.pk}_i, \text{WKEnc.pk}_i, \text{vk}_i, \mathbf{C}_{\text{PRF}})$  and  $\text{SK}_i = (\text{FHE.sk}_i, \text{WKEnc.sk}_i, \text{sk}_i, k)$

We prove in Lemma 3 that the two hybrids are indistinguishable.

- **Hybrid<sub>5</sub>**: This hybrid is the same as **Hybrid<sub>4</sub>**, except that the upon receiving a SUBMIT command, the PRFOut is replaced by a random value. By the pseudorandomness property of the underlying PRF scheme, the two hybrids are indistinguishable.

Protocol SubmitXfer(tx, C<sub>loc</sub>)

1. If  $\text{tx} = (\text{TRANSFER}, \text{tx}')$ 
  - (a) Let  $(\text{PK}^*, \text{SK}^*) \leftarrow \text{KEYGENERATION}(\lambda)$
  - (b) Set  $x = 0$
  - (c) Use the clock to update  $\tau, ep \leftarrow \lceil \tau/R \rceil$  and  $sl \leftarrow \tau$
  - (d) Let  $\mathcal{C}_{\text{loc}}$  be the chain upto the beginning of the epoch  $ep$ .
  - (e) Let  $(\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi) := \text{TRANSFER}(\text{PK}^*, \text{PK}^*, x, ep, R, \mathcal{C}_{\text{loc}})$
  - (f) Sample  $y \leftarrow \{0, 1\}^\lambda$  and replace PRFOut with  $y$ .
  - (g) Submit  $(\text{MULTICAST}, \text{tx})$  to  $\mathcal{F}_{\text{N-MC}}$
2. Else if  $\text{tx} = (\text{MINT}, \text{tx}') \dots$

We prove in Lemma 4 that the two hybrids are indistinguishable.

- **Hybrid<sub>6</sub>**: This hybrid is the same as **Hybrid<sub>5</sub>** except that the upon receiving a registration request, replace  $k\text{-ct}_i$  with  $\text{FHE.Enc}(\text{FHE.pk}_i, 0)$  instead of encrypting  $\text{WKEnc.sk}_i$ . By the CPA security of the underlying FHE scheme, the two hybrids are indistinguishable.

KEYGENERATION( $\lambda$ ): User  $P_i$  does:

1. Key Generation: ...
2. Encrypting WKEnc keys:
  - $k\text{-ct}_i \leftarrow \text{FHE.Enc}(\text{FHE.pk}_i, 0), \dots, \text{FHE.Enc}(\text{FHE.pk}_i, 0)$
3. Committing to PRF key: ...
4. Return  $\text{PK}_i := (k\text{-ct}_i, \text{FHE.pk}_i, \text{WKEnc.pk}_i, \text{vk}_i, \mathbf{C}_{\text{PRF}})$  and  $\text{SK}_i = (\text{FHE.sk}_i, \text{WKEnc.sk}_i, \text{sk}_i, k)$

We prove in Lemma 5 that the two hybrids are indistinguishable.

- **Hybrid<sub>7</sub>**: This hybrid is the same as **Hybrid<sub>6</sub>** except that the simulator may now abort with sigFailure. Since we use unforgeable signatures the simulator aborts with negligible probability and therefore the two hybrids are indistinguishable.

If tx is a MINT transaction:

1. Parse tx as  $(\text{tx}', \sigma)$  where  $\text{tx}' = (v, \text{PK}_i, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}})$
2. If  $\sigma$  corresponds to that of an honest party abort with sigFailure.
3. ...

We prove in Lemma 6 that the two hybrids are indistinguishable.

- **Hybrid<sub>8</sub>**: This hybrid is the same as **Hybrid<sub>7</sub>** except that the simulator may now abort with ZKSoundnessFailure. By the soundness property of the underlying zero knowledge scheme, this occurs with negligible probability.

If tx is a TRANSFER transaction:

1. Parse tx as  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi$
2. Check that  $(\pi, (\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_C, \mathbf{C}_D, \mathbf{C}_{\text{PRF}}, \text{rt}_{\mathcal{T}_{\text{privAccounts}}}, ep), w)$  exists in  $\Pi$  as was recorded by the simulation of  $\mathcal{F}_{\text{nizk}}$  towards the adversary. If such an entry does not exist, abort with ZKSoundnessFailure
3. ...

This event occurs with negligible probability since we use the  $\mathcal{F}_{\text{nizk}}$  ideal functionality to compute zero knowledge proofs.

- **Hybrid<sub>9</sub>**: This hybrid is the same as **Hybrid<sub>8</sub>** except that the simulator may now abort with CRHFailure. Since we use collision-resistant hash functions, this event occurs with negligible probability.

If tx is a TRANSFER transaction:

1. Parse tx as  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi$
2. ...
3. Else parse  $w$  as  $(\text{PK}_S, \text{SK}_S, \text{PK}_R, v, v_S, \mathbf{C}, \text{path})$ . If  $(\text{PK}_S, \mathbf{C}) \notin \mathcal{T}_{\text{privAccounts}}$  but  $\text{VerifyPath}(\text{rt}_{\text{privAccounts}}, \text{path}) = 1$ , abort with **CRHFailure**.

We prove in Lemma 7 that the two hybrids are indistinguishable.

- **Hybrid<sub>10</sub>**: This hybrid is the same as **Hybrid<sub>9</sub>**, except that the simulator may now abort with **CommFailure**. Since we use statistically-binding commitments, this event occurs with negligible probability.

If tx is a **TRANSFER** transaction:

1. Parse tx as  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C, \text{PRFOut}, \pi$
2. ...
3. Let  $\text{SK}_S = (\text{FHE.sk}_S, \text{WKEnc.sk}_S, \text{sk}_S, k_S)$  and from  $\Pi_{\text{KEYGEN}}$ , find the record  $(\pi, \text{PK}_S, w^*)$  and let  $w = (\text{FHE.sk}_S, \text{WKEnc.sk}_S, \text{sk}_S, k_S^*)$ . If  $k_S^* \neq k_S$ , abort with error **CommFailure**.

We prove in Lemma 8 that the two hybrids are indistinguishable.

- **Hybrid<sub>11</sub>**: This hybrid is the same as **Hybrid<sub>10</sub>** except that the simulator may now abort with **PRFFailure**. Since we use PRF with the property of unpredictability malicious key generation, this occurs with negligible probability.

Finally this hybrid is the same as the ideal world, and therefore the real world and the ideal world are indistinguishable.

**Lemma 1.** *By the CPA security over multiple encryptions[29] of the underlying encryption scheme **WKEnc**, **Hybrid<sub>1</sub>** and **Hybrid<sub>2</sub>** are indistinguishable to a PPT adversary.*

*Proof.* The difference between **Hybrid<sub>1</sub>** and **Hybrid<sub>2</sub>** is that the simulator replaces the encryptions  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C$  with encryptions of 0.

Assume a distinguisher  $D$  can distinguish between **Hybrid<sub>1</sub>** and **Hybrid<sub>2</sub>**, i.e.  $\Pr[D(\mathbf{Hybrid}_1) = 1] - \Pr[D(\mathbf{Hybrid}_2) = 1] > \text{negl}$

Using this distinguisher  $D$  we construct a reduction  $B$  that can break the CPA security of encryption scheme.

**Reduction  $B$ :**

1. Activate the distinguisher  $D$
2. The reduction simulates the protocol  $\Pi_{\text{PriFHEte}}$  as in **Hybrid<sub>1</sub>**.
3. Send  $\mathbf{m}_0 = (\text{PK}_1, \text{PK}_2, x, x)$  and  $\mathbf{m}_1 = (0, 0, 0, 0)$  to the challenger and receive  $\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_3, \mathbf{C}_4$
4. Instruct the environment to submit a transaction  $(\text{PK}_1, \text{PK}_2, x)$ , and replace the ciphertexts in the transfer transaction with  $\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_3, \mathbf{C}_4$ .
5. Submit tx to  $\mathcal{F}_{\text{N-MC}}$ .
6. Output whatever  $D$  outputs.

Note that in the case  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C$  was the encryption of  $m_0$  the distinguisher sees the hybrid world - **Hybrid<sub>1</sub>** and on the other hand when encryption of  $m_1$  is returned the distinguisher sees the hybrid world **Hybrid<sub>2</sub>**.

Now since  $\Pr[D(\mathbf{Hybrid}_1) = 1] - \Pr[D(\mathbf{Hybrid}_2) = 1] > \text{negl}$ , we have that  $\text{Adv}_{\text{CPA}} > \text{negl}$  which is a contradiction since we assume CPA secure encryption over multiple encryptions. This implies  $\Pr[D(\mathbf{Hybrid}_1) = 1] - \Pr[D(\mathbf{Hybrid}_2) = 1] = \text{negl}$ .

**Lemma 2.** *By the key-privacy property (Def 2) of the underlying encryption scheme, the hybrids **Hybrid<sub>2</sub>** and **Hybrid<sub>3</sub>** are indistinguishable.*

*Proof.* The difference between **Hybrid<sub>2</sub>** and **Hybrid<sub>3</sub>** is that the simulator replaces the encryptions  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C$  with encryptions under a freshly generated key  $\text{WKEnc.pk}^*$  where  $(\text{WKEnc.pk}^*, \text{WKEnc.sk}^*) = \text{WKEnc.KeyGen}(\lambda)$ .

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>2</sub> and **Hybrid**<sub>3</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_2) = 1] - Pr[D(\mathbf{Hybrid}_3) = 1] > \text{negl}$

Using this distinguisher  $D$  we construct a reduction  $B$  that can break the IK-CPA security of encryption scheme.

**Reduction  $B$ :**

1. Activate the distinguisher  $D$
2. Receive two public keys  $pk_0, pk_1$  from the challenger.
3. The reduction simulates the protocol  $\Pi_{\text{PriFHEte}}$  as in **Hybrid**<sub>2</sub>, such that  $\text{WKEnc.pk}_i$  of a party  $P_i$  is replaced with  $pk_0$
4. Send  $\text{WKEnc.pk}_R, \text{WKEnc.pk}_S, v, v$  to the challenger and receive  $\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_3, \mathbf{C}_4$ .
5. Instruct the environment to submit a transaction  $(PK_1, PK_2, x)$ , and replace the ciphertexts in the transfer transaction with  $\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_3, \mathbf{C}_4$ .
6. Submit tx to  $\mathcal{F}_{\text{N-MC}}$ .
7. Output whatever  $D$  outputs.

Note that in the case  $\mathbf{C}_S, \mathbf{C}_R, \mathbf{C}_D, \mathbf{C}_C$  was encrypted under  $pk_0$  the distinguisher sees the hybrid world - **Hybrid**<sub>2</sub> and on the other hand when encryptions are under  $pk_1$  the distinguisher sees the hybrid world **Hybrid**<sub>3</sub>.

Now since  $Pr[D(\mathbf{Hybrid}_2) = 1] - Pr[D(\mathbf{Hybrid}_3) = 1] > \text{negl}$ , we have that  $\text{Adv}_{\text{IK-CPA}} > \text{negl}$  which is a contradiction since we assume IK-CPA secure encryption over multiple encryptions. This implies  $Pr[D(\mathbf{Hybrid}_2) = 1] - Pr[D(\mathbf{Hybrid}_3) = 1] = \text{negl}$ .

**Lemma 3.** *By the hiding property of the underlying commitment scheme, **Hybrid**<sub>3</sub> and **Hybrid**<sub>4</sub> are indistinguishable to a PPT adversary.*

*Proof.* The difference between **Hybrid**<sub>3</sub> and **Hybrid**<sub>4</sub> is that the simulator replaces the commitment to the PRF key with a commitment to 0.

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>3</sub> and **Hybrid**<sub>4</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_3) = 1] - Pr[D(\mathbf{Hybrid}_4) = 1] > \text{negl}$

Using this distinguisher  $D$  we construct a reduction  $B$  that can break the hiding property of the commitment scheme.

**Reduction  $B$ :**

1. Activate the distinguisher  $D$
2. The reduction simulates the protocol  $\Pi_{\text{PriFHEte}}$  as in **Hybrid**<sub>3</sub>.
3. Let  $PK_i$  be the public key of an honest party  $P_i$
4. Send  $m_0 = k$  and  $m_1 = 0$  to the challenger and receive  $C$
5. Replace the  $C_{\text{PRF}}$  in  $PK_i$  with  $C$  for party  $P_i$
6. Instruct the environment to submit a transaction  $(\text{NEW-PARTY}, PK_i)$
7. Submit tx to  $\mathcal{F}_{\text{N-MC}}$ .
8. Output whatever  $D$  outputs.

Note that in the case  $C$  was the encryption of  $m_0$  the distinguisher sees the hybrid world - **Hybrid**<sub>3</sub> and on the other hand when encryption of  $m_1$  is returned the distinguisher sees the hybrid world **Hybrid**<sub>4</sub>.

Now since  $Pr[D(\mathbf{Hybrid}_3) = 1] - Pr[D(\mathbf{Hybrid}_4) = 1] > \text{negl}$ , we have that  $\text{Adv}_{\text{CommHiding}} > \text{negl}$  which is a contradiction since we assume a secure commitment scheme. This implies  $Pr[D(\mathbf{Hybrid}_3) = 1] - Pr[D(\mathbf{Hybrid}_4) = 1] = \text{negl}$ .

**Lemma 4.** *By the pseudorandomness property of the underlying PRF scheme, the hybrids **Hybrid**<sub>4</sub> and **Hybrid**<sub>5</sub> are indistinguishable.*

*Proof.* The difference between **Hybrid**<sub>4</sub> and **Hybrid**<sub>5</sub> is that the simulator replaces the PRFOut with a randomly sampled  $y \leftarrow \{0, 1\}^\ell$

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>4</sub> and **Hybrid**<sub>5</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_4) = 1] - Pr[D(\mathbf{Hybrid}_5) = 1] > \text{negl}$

Using this distinguisher  $D$  we construct a reduction  $B$  that can break the pseudorandomness property of the underlying PRF scheme.

**Reduction  $B$ :**

1. Activate the distinguisher  $D$
2. The reduction simulates the protocol  $\Pi_{\text{PriFHE}_{\text{te}}}$  as in **Hybrid**<sub>4</sub>
3. Send  $ep$  the current epoch number to the challenger and receive  $y$ .
4. Instruct the environment to submit a transaction  $(\text{PK}_1, \text{PK}_2, x)$ , and replace the PRFOut in the transfer transaction with  $y$ .
5. Submit tx to  $\mathcal{F}_{\text{N-MC}}$ .
6. Output whatever  $D$  outputs.

Note that in the case PRFOut was computed using  $\text{PRF}(k, \cdot)$  the distinguisher sees the hybrid world - **Hybrid**<sub>4</sub> and on the other hand when PRF output is a random  $y \leftarrow \{0, 1\}^\ell$  the distinguisher sees the hybrid world **Hybrid**<sub>5</sub>.

Now since  $Pr[D(\mathbf{Hybrid}_4) = 1] - Pr[D(\mathbf{Hybrid}_5) = 1] > \text{negl}$ , we have that advantage of the adversary winning the PRF pseudorandomness game which is a contradiction since we assume secure PRFs. This implies  $Pr[D(\mathbf{Hybrid}_4) = 1] - Pr[D(\mathbf{Hybrid}_5) = 1] = \text{negl}$ .

**Lemma 5.** *By the CPA security over multiple encryptions[29] of the underlying encryption scheme FHE, **Hybrid**<sub>5</sub> and **Hybrid**<sub>6</sub> are indistinguishable to a PPT adversary.*

*Proof.* The difference between **Hybrid**<sub>5</sub> and **Hybrid**<sub>6</sub> is that the simulator replaces the encryptions k-ct with encryptions of 0.

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>5</sub> and **Hybrid**<sub>6</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_5) = 1] - Pr[D(\mathbf{Hybrid}_6) = 1] > \text{negl}$

Using this distinguisher  $D$  we construct a reduction  $B$  that can break the CPA security of encryption scheme.

**Reduction  $B$ :**

1. Activate the distinguisher  $D$
2. The reduction simulates the protocol  $\Pi_{\text{PriFHE}_{\text{te}}}$  as in **Hybrid**<sub>5</sub>.
3. Let  $\text{PK}_i$  be the public key of an honest party  $P_i$
4. Send  $\mathbf{m}_0 = \text{WKEnc.sk}_i$  and  $\mathbf{m}_1 = \mathbf{0}$  to the challenger and receive  $c$
5. Replace the k-ct <sub>$i$</sub>  with  $c$  for party  $P_i$
6. Instruct the environment to submit a transaction  $(\text{PK}_i, \text{PK}_j, x)$  where  $P_j$  is another party.
7. Submit tx to  $\mathcal{F}_{\text{N-MC}}$ .
8. Output whatever  $D$  outputs.

Note that in the case k-ct <sub>$i$</sub>  was the encryption of  $m_0$  the distinguisher sees the hybrid world - **Hybrid**<sub>5</sub> and on the other hand when encryption of  $m_1$  is returned the distinguisher sees the hybrid world **Hybrid**<sub>6</sub>.

Now since  $Pr[D(\mathbf{Hybrid}_5) = 1] - Pr[D(\mathbf{Hybrid}_6) = 1] > \text{negl}$ , we have that  $\text{Adv}_{\text{CPA}} > \text{negl}$  which is a contradiction since we assume CPA secure encryption over multiple encryptions. This implies  $Pr[D(\mathbf{Hybrid}_5) = 1] - Pr[D(\mathbf{Hybrid}_6) = 1] = \text{negl}$ .

**Lemma 6.** *Assuming existential unforgeable signatures that are secure against chosen message attacks, **Hybrid**<sub>6</sub> and **Hybrid**<sub>7</sub> are indistinguishable.*

*Proof.* Note that the difference between **Hybrid**<sub>6</sub> and **Hybrid**<sub>7</sub> is that in **Hybrid**<sub>6</sub> the event **sigFailure**<sub>1</sub> can occur. We prove in this section that the probability of this event occurring is negligible.

First we observe that **sigFailure** occurs when the simulator receives a MINT transaction from the adversary that contains a signature that corresponds to that of an honest party.

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>6</sub> and **Hybrid**<sub>7</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_6) = 1] - Pr[D(\mathbf{Hybrid}_7) = 1] > \text{negl}$

This implies that  $Pr[\text{sigFailure}] > \text{negl}$ .

Using this adversary we present a reduction  $B$  that breaks the EUF-CMA property of signature schemes.

Reduction  $B$

1. Receive  $vk$  from the challenger. Update  $PK_i$  of an honest party  $P_i$  with  $vk$ .
2. Simulate the world as in **Hybrid**<sub>6</sub>.
3. Upon receiving a MINT transaction via the  $\mathcal{F}_{N-MC}$  functionality, check if the signature  $\sigma'$  corresponds to that of  $vk$ . If not, ignore.
4. If yes, output  $m = (PK_i, x, rt_{\mathcal{T}_{\text{pubAccounts}}})$  and  $\sigma = \sigma'$

Observe that

$$\begin{aligned} \text{Adv}_{\Sigma, \mathcal{A}}^{\text{euf-cma}} &= Pr[\mathbf{Exp}_{\Sigma, \mathcal{A}}^{\text{euf-cma}}(\lambda) = 1] \\ &= Pr[\Sigma.\text{Verify}(vk, m\sigma) = 1] > \text{negl} \end{aligned}$$

But this is a contradiction since we assume EUF-CMA signatures and therefore  $\text{Adv}_{\Sigma, \mathcal{A}}^{\text{euf-cma}} < \text{negl}$   
Hence  $Pr[\text{sigFailure}] < \text{negl}$  and therefore  $Pr[D(\mathbf{Hybrid}_6) = 1] - Pr[D(\mathbf{Hybrid}_7) = 1] < \text{negl}$

**Lemma 7.** *Assuming collision-resistant hash functions, **Hybrid**<sub>8</sub> and **Hybrid**<sub>9</sub> are indistinguishable to a PPT adversary*

*Proof.* Note that the difference between **Hybrid**<sub>8</sub> and **Hybrid**<sub>9</sub> is that in **Hybrid**<sub>8</sub> the event **CRHFailure**<sub>1</sub> can occur. We prove in this section that the probability of this event occurring is negligible.

First we observe that **CRHFailure** occurs when the simulator receives a TRANSFER transaction from the adversary that contains a **path** that does not correspond to a path from an account and balance in  $\mathcal{T}_{\text{privAccounts}}$  owned by the sender to the root of the Merkle tree computed over  $\mathcal{T}_{\text{privAccounts}}$

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>8</sub> and **Hybrid**<sub>9</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_8) = 1] - Pr[D(\mathbf{Hybrid}_9) = 1] > \text{negl}$

This implies that  $Pr[\text{CRHFailure}] > \text{negl}$ .

Using this adversary we present a reduction  $B$  that breaks the collision resistance property of the underlying hash scheme.

Reduction  $B$

1. Simulate the world as in **Hybrid**<sub>8</sub>.
2. Upon receiving a TRANSFER transaction via the  $\mathcal{F}_{N-MC}$  functionality, get the witness  $w$  that corresponds to the proof  $\pi$  in the transaction.
3. Let **path**<sup>\*</sup> be the path in the Merkle tree (computed over  $\mathcal{T}_{\text{privAccounts}}$ ) from  $(PK_{\mathcal{A}}, v_{\mathcal{A}})$  to the root of the Merkle root  $rt_{\text{privAccounts}}$ .
4. Let  $w = (PK_S, SK_S, PK_R, v, v_S, \mathbf{C}, \text{path})$  and  $\text{VerifyPath}(rt_{\mathcal{T}_{\text{privAccounts}}}, \text{path}) = 1$
5. If  $(PK_S, v_S)$  does not correspond to the adversary's entry in  $\mathcal{T}_{\text{privAccounts}}$ , output  $(m_0 = \text{path}, m_1 = \text{path}^*)$

Observe that

$$\text{Adv}_{\mathcal{H}, \mathcal{A}}^{\text{CRHF}} = Pr[\exists m_0, m_1 \text{ s.t. } \mathcal{H}(m_0) = \mathcal{H}(m_1)] > \text{negl}$$

But this is a contradiction since we assume collision-resistant hash functions and therefore  $\text{Adv}_{\mathcal{H}, \mathcal{A}}^{\text{CRHF}} < \text{negl}$

Hence  $Pr[\text{CRHFailure}] < \text{negl}$  and therefore  $Pr[D(\mathbf{Hybrid}_8) = 1] - Pr[D(\mathbf{Hybrid}_9) = 1] < \text{negl}$

**Lemma 8.** *Assuming statistically binding commitments, the hybrids **Hybrid**<sub>9</sub> and **Hybrid**<sub>10</sub> are indistinguishable.*

*Proof.* Note that the difference between **Hybrid**<sub>9</sub> and **Hybrid**<sub>10</sub> is that in **Hybrid**<sub>9</sub> the event **CommFailure** can occur. We prove in this section that the probability of this event occurring is negligible.

First we observe that **CommFailure** occurs when the simulator receives a **TRANSFER** transaction from the adversary and the PRF key in the extracted witness from this transaction is not the same as the PRF key that was committed to.

Assume a distinguisher  $D$  can distinguish between **Hybrid**<sub>9</sub> and **Hybrid**<sub>10</sub>, i.e.  $Pr[D(\mathbf{Hybrid}_9) = 1] - Pr[D(\mathbf{Hybrid}_{10}) = 1] > \text{negl}$

This implies that  $Pr[\mathbf{CommFailure}] > \text{negl}$ .

Using this adversary we present a reduction  $B$  that breaks the binding property of the underlying commitment scheme.

Reduction  $B$

1. Simulate the world as in **Hybrid**<sub>9</sub>.
2. Upon receiving a **TRANSFER** transaction via the  $\mathcal{F}_{\text{N-MC}}$  functionality, get the witness  $w$  that corresponds to the proof  $\pi$  in the transaction.
3. Retrieve  $k_S$  from  $w$ .
4. From  $\Pi_{\text{KeyGen}}$ , retrieve the record for  $\text{sk}_S$  read  $k_{S^*}$
5. If  $k_S \neq k_{S^*}$  output  $(m_0 = \text{path}, m_1 = \text{path}^*)$  and  $\text{C}_{\text{PRF}}$ .

Observe that

$$\text{Adv}_{\mathcal{A}}^{\text{Com}} = Pr[\exists m_0, m_1 \text{ s.t. } \text{Open}(\text{C}_{\text{PRF}}) = k_S = k_{S^*}] > \text{negl}$$

But this is a contradiction since we assume collision-resistant hash functions and therefore  $\text{Adv}_{\mathcal{A}}^{\text{Com}} < \text{negl}$

Hence  $Pr[\mathbf{CommFailure}] < \text{negl}$  and therefore  $Pr[D(\mathbf{Hybrid}_9) = 1] - Pr[D(\mathbf{Hybrid}_{10}) = 1] < \text{negl}$

## E Regev Cryptosystem and Wrong-Key Decryption

The Regev cryptosystem is parameterized by integers  $n$  (the security parameter),  $m$  (number of equations), and a real  $\alpha > 0$  (noise parameter). All operations are done modulo  $q$  (a prime)

- **Setup:** Choose a prime  $q \leftarrow_{\mathcal{S}} [n^2, 2n^2]$ ,  $m = 1.1 \cdot n \log q$  and  $\alpha = 1/(\sqrt{n} \log^2 n)$
- **Key Generation:** Private key is a vector  $\mathbf{s} \leftarrow \mathbb{Z}_q^n$  and the public key consists of  $m$  samples  $(\mathbf{a}_i, b_i)_{i=1}^m$  from the LWE distribution with secret  $\mathbf{s}$ , modulus  $q$  and error parameter  $\alpha$ . That is,  $\mathbf{a}_i \leftarrow_{\mathcal{S}} \mathbb{Z}_q^n$  and  $b_i = \mathbf{s}^T \mathbf{a}_i + e_i$  where  $e_i$  is error sampled from error distribution  $\chi$  for  $i \in [m]$
- **Encryption:** For each bit of the message do the following. Choose a random set  $S$  uniformly among all  $2^m$  subsets of  $[m]$ . The encryption is  $(\sum_{i \in S} \mathbf{a}_i, \sum_{i \in S} b_i)$  if the bit is 0 and  $(\sum_{i \in S} \mathbf{a}_i, \lfloor \frac{q}{2} \rfloor + \sum_{i \in S} b_i)$  if the bit is 1.
- **Decryption:** The decryption of a pair  $(\mathbf{a}, b)$  is 0 if  $b - \langle \mathbf{a}, \mathbf{s} \rangle$  is closer to 0 than to  $\lfloor \frac{q}{2} \rfloor \pmod q$ , and 1 otherwise.

**Lemma 9.** *Regev's encryption scheme described above satisfies the property of wrong-key decryption (Def 3).*

*Proof.* Let  $(\text{sk}, \text{pk})$  be  $(\mathbf{s}^*, (\mathbf{a}_i^*, b_i^*)_{i=1}^m)$  and let  $(\text{sk}', \text{pk}')$  be  $(\mathbf{s}^\dagger, (\mathbf{a}_i^\dagger, b_i^\dagger)_{i=1}^m)$

Now,

$$\text{ct} \leftarrow \text{WKEnc.Enc}(\text{pk}, 1)$$

$$\implies \text{ct} = \left( \sum_{i \in S} \mathbf{a}_i^*, \left\lfloor \frac{q}{2} \right\rfloor + \sum_{i \in S} b_i^* \right)$$

Furthermore let  $\text{ct} = (\mathbf{a}, b)$  then,

$$\begin{aligned} m' &= \text{WKEnc.Dec}(\text{sk}', \text{ct}) \\ \implies m' &= b - \langle \mathbf{a}, \mathbf{s}^\dagger \rangle \pmod{q} \\ \implies m' &= \left( \left\lfloor \frac{q}{2} \right\rfloor + \sum_{i \in S} b_i^* \right) - \left( \sum_{i \in S} a_{i,1}^* s_1^\dagger + \dots + \sum_{i \in S} a_{i,n}^* s_n^\dagger \right) \pmod{q} \\ \implies m' &= \left( \left\lfloor \frac{q}{2} \right\rfloor + \sum_{i \in S} a_{i,1}^* s_1^* + e_1 \dots + \sum_{i \in S} a_{i,n}^* s_n^* + e_n - \sum_{i \in S} a_{i,1}^* s_1^\dagger + \dots + \sum_{i \in S} a_{i,n}^* s_n^\dagger \right) \pmod{q} \\ \implies m' &= \left( \left\lfloor \frac{q}{2} \right\rfloor + (s_1^* - s_1^\dagger) \sum_{i \in S} a_{i,1}^* \dots + (s_n^* - s_n^\dagger) \sum_{i \in S} a_{i,n}^* + (e_1 + \dots + e_n) \right) \pmod{q} \end{aligned}$$

Since  $\mathbf{a}_i^*, e_i$  and  $\mathbf{s}$  are all sampled randomly:

$$m' = \text{uniformly random element in } \mathbb{Z}_q$$

Thus,

$$m' > \frac{q}{2} \text{ with probability } \frac{1}{2}$$

Therefore

$$\Pr[m' = 1] \leq 1/2 + \text{negl}(\lambda)$$

## F Full adder and subtracter

Let  $\mathbf{a} = \{a_1, \dots, a_\mu\}$  and  $\mathbf{b} = \{b_1, \dots, b_\mu\}$  be two vectors where each  $a_i, b_i \in \{0, 1\}$ . We present a full adder below that computes  $\mathbf{c} = \mathbf{a} + \mathbf{b}$ .

**FullAdder**( $\mathbf{a}, \mathbf{b}$ )

1. Set  $\text{cin} = 0$
2. For  $i \in [\mu]$  :
  - (a) Compute  $c_i = \text{cin} \oplus a_i \oplus b_i$
  - (b) Compute  $\text{cin} = a_i b_i \oplus b_i \text{cin} \oplus a_i \text{cin}$
3. Return  $(\text{cin}, c_1, \dots, c_\mu)$

**Fig. 30.** Full Adder

Below we describe a full subtracter that computes  $\mathbf{c} = \mathbf{a} - \mathbf{b}$

```

FullSubtractor(a, b)
1. Set cin = 0
2. For  $i \in [\mu]$  :
   (a) Compute  $c_i = \text{cin} \oplus a_i \oplus b_i$ 
   (b) Compute  $\text{cin} = (\neg a_i)b_i \oplus b_i\text{cin} \oplus (\neg a_i)\text{cin}$ 
3. Return (cin,  $c_1, \dots, c_\mu$ )

```

Fig. 31. Full Adder

## G Potential for Deployment

As discussed in the introduction, the PriFHEte algorithms can be deployed as smart contracts. In this section, we discuss how our algorithms can be deployed on Ethereum. Next we discuss how we can alleviate the computation of miners by deploying PriFHEte as zk-rollups[21] which are a new scalability solution for Ethereum.

### G.1 Background on Ethereum and Smart Contracts

*Accounts.* Ethereum is an account-based cryptocurrency. There are two types of accounts in Ethereum - Externally Owned Accounts (EOA) and Contract Accounts. An EOA is associated with signature public key/private key pair and anyone who knows the private key can control the account. On the other hand, a Contract Account is controlled by the code of the smart contract. Now what is a smart contract? It's a collection of code (its functions) and data (its state) that resides at a specific address on the Ethereum blockchain. This address is simply the hash of the public key of the creator of the smart contract.

*State of the blockchain.* In Ethereum the state is a data structure called a modified Merkle Patricia tree, where the leaves of this tree are the accounts (both EOA and contract accounts). Each leaf is an address, data pair. The data for EOA accounts includes the balance associated to the address, and the data field of contract accounts include the code and the state of the contract.

*Transactions.* In Ethereum, there are three types of transactions.

1. A *regular transaction*, that transfers funds from one EOA to another EOA.
2. A *contract deployment transaction*, which deploys a smart contract on Ethereum. This transaction includes the code of the smart contract, and the address of the smart contract.
3. A *contract execution transaction*, which is addressed to one of the deployed smart contracts. This transaction may include inputs to the functions of the smart contract that are to be executed. Upon receiving this transaction, a miner executes the smart contract and updates the state of the smart contract and therefore the state of Ethereum.

### G.2 PriFHEte as a smart contract

To describe the deployment of PriFHEte, we need to specify three different aspects: the setup, description of the smart contract, and the user algorithms. We will show how the algorithms described in Section 4 can be cast as smart contract functions and user algorithms.

**The setup** In the setup phase, public parameters such as the CRS are generated. Some entity, will also submit a Contract Deployment Transaction with the code for the PriFHEte smart contract. A miner updates the state by adding a smart contract account. The state of this account includes an empty table that will maintain account/encrypted balance pairs.

**The smart contract.** The smart contract has two functions:  $\text{REGISTRATION}(\text{PK}, \mathcal{T}) \rightarrow \mathcal{T}'$  and  $\text{PROCESSTRANSACTION}(\text{tx}, \mathcal{T}) \rightarrow \mathcal{T}'$

Observe that the two functions take as input the state  $\mathcal{T}$  and output an updated state  $\mathcal{T}'$ . This is the internal state of the smart contract which is simply a table of account-encrypted balance pairs. The  $\text{REGISTRATION}$  function appends a new row with  $\text{PK}$  and an encryption to 0 under  $\text{FHE.pk}$  to the  $\mathcal{T}$ . Similarly  $\text{PROCESSTRANSACTION}$  processes a transaction as discussed in Figure 8 and updates *all rows* of the state.

**User Algorithms** A user runs one of the following algorithms to interact with PriFHEte smart contract.

The output of these algorithms are contract execution transactions, which are addressed to the PriFHEte smart contract.

1.  $\text{KEYGENERATION}(\lambda) \rightarrow (\text{PK}, \text{SK})$ . With this transaction the user registers with the smart contract and joins the PriFHEte system. This transaction invokes the  $\text{REGISTRATION}$  function of the smart contract.
2.  $\text{MINT}(\text{PK}_i, \text{PK}_i^{\text{pub}}, \text{SK}_i^{\text{pub}}, x, \text{rt}_{\mathcal{T}_{\text{pubAccounts}}}) \rightarrow (\text{tx}_{\text{MINT}}, \sigma)$ . With this transaction the user invokes a function that transfers funds from the main chain to the the PriFHEte smart contract. This transaction invokes the  $\text{PROCESSTRANSACTION}$  function of the smart contract.
3.  $\text{TRANSFER}(\text{PK}_S, \text{SK}_S, \text{PK}_R, x, ep, R, \mathcal{C}_{\text{loc}}^S, \text{path}_i, \mathbf{C}_i) \rightarrow \text{tx}_{\text{TRANSFER}}$ . With this transaction the user invokes a function that transfers funds from one account to another maintained by the PriFHEte smart contract. This transaction invokes the  $\text{PROCESSTRANSACTION}$  function of the smart contract.

### G.3 Alleviating storage and computation costs for the miners

As discussed in the introduction, we envision zk-rollups[21] to aid the storage and computation costs of the miners. Below we first describe how rollups work and then briefly describe how the PriFHEte algorithms could be deployed as a rollup. We observe that this is the same approach taken by AZTEC[48] to achieve privacy. The main difference between their work and ours is that they do a UTXO-style transactions on top of Ethereum, whereas we dont depart from the account-based paradigm. They use stealth address to achieve anonymity. This doesnt give full anonymity, since the sender of a transaction can always trace how the receiver is going to spend the coin.

**Zero Knowledge (ZK) Rollups:** There are three entities in a rollup protocol. The users, the miners and rollup operators. Rollup operators execute transactions off-chain. This reduces the amount of computation and the storage that miners need to do. These operators submit a summary of changes as well as validity proofs to prove correctness of the summary of changes. A miner can verify this validity proof to be convinced that the received state is a result of the execution of all the transactions in a batch.

The rollup architecture is comprised of two components:

- On-chain contract: this contract includes code to keep track of the updated state (which is a succinct representaion of the total state) and also code to verify validity proofs
- Off-chain computation: this is done by rollup operators that maintain the entire state, execute the transactions, compute validity proofs and compute succinct representations of the updated state.

**PriFHEte as a rollup** Users submit their transactions to the rollup operators. The rollups execute these transactions in batches and update the maintained state. The operators then submit a succinct representation of the state, along with validity proofs and the transactions to the main chain network. A miner verifies the validity proofs by executing the verifier function of the rollup smart contract. They then update the smart contract state with the received succinct representation of state.

We note that while we do not need to trust a rollup operator for privacy, we trust that they will include transactions of users.

Finally, we note using rollups help with gas fees because there is a fixed cost to writing to Ethereum's state. Without rollups each transaction would update  $O(N)$  data entries of the state whereas with rollups one needs to update only a single data entry for multiple transactions. Therefore a rollup reduces this fixed cost by spreading the it across many users.
